## ABSTRACT

We report results of *VRI* photometric monitoring of the T Tauri star plus disk system HH 30 IRS. We find that HH 30 IRS is highly variable over timescales of a few days with $\Delta V \sim 1.5$ mag, $\Delta I \sim 1.1$ mag. Furthermore, we find hints of periodicity with periodograms indicating possible periods of 11.6 and 19.8 days. The *VRI* photometry is available through the ANONYMOUS FTP service. We model the variability with Monte Carlo radiation transfer simulations for a spotted star plus disk system and find that the large variability is best reproduced with a single hot spot and circumstellar grains that are larger than typical interstellar grains. The apparent existence of a single hot spot and the need for larger, more forward-throwing grains is consistent with previous modeling of *Hubble Space Telescope* imagery.

*Subject headings:* accretion, accretion disks — radiative transfer — stars: individual (HH 30) —
stars: pre–main-sequence — stars: rotation — stars: spots

## 1. INTRODUCTION

Signatures of hot and cool starspots have been observed in numerous T Tauri stars, primarily in the form of photometric variability, with *periodic* variability detected in hundreds of systems (e.g., Bouvier et al. 1993; Wichmann et al. 1998; Choi & Herbst 1996; Makidon et al. 1997; Stassun et al. 1999). While cool spots have been mapped through Doppler imaging of weak-lined T Tauri stars (e.g., Hatzes 1995), hot spots tend to be associated with variability in classical T Tauri stars (e.g., Kenyon et al. 1994; Bouvier et al. 1993; Herbst et al. 1994). The hot spots are thought to be associated with the accretion process, and the currently favored magnetic accretion models naturally provide for hot spots on stellar surfaces (Ghosh & Lamb 1979a, 1979b; Königl 1991; Shu et al. 1994; Ostriker & Shu 1995; Najita 1995).

Hot spots yield specific brightness and polarization variations as they rotate into and out of view (Wood et al. 1996; Mahdavi & Kenyon 1998; Stassun & Wood 1999). Wood & Whitney (1998) investigated the effects of hot starspots on the morphology of scattered light disks. The nonaxisymmetric illumination of the disk by hot spots leads to an asymmetric brightening of the disk. Such asymmetric brightening has been detected in *Hubble Space Telescope* (*HST*) observations of the edge-on disk system HH 30 IRS (Burrows et al. 1996; Stapelfeldt et al. 1999a), hinting at possible agreement with the magnetic accretion model.

The gross consistency between the existing observations of HH 30 IRS and the predictions of the magnetic accretion model is tantalizing but ambiguous because of the large timescales separating the *HST* observations. Periodic variability due to magnetic accretion is expected to match the rotational periods for classical T Tauri stars—of the order less than 1 day to tens

of days (Attridge & Herbst 1992; Bouvier et al. 1993; Edwards et al. 1993; Eaton et al. 1995; Stassun et al. 1999; Herbst et al. 2000). In some cases the hot spots are stable over many rotation periods.

Motivated by the apparent success of the magnetic accretion model at explaining the morphological variations observed in the limited *HST* imagery, we have undertaken a ground-based photometric monitoring campaign on HH 30 IRS to determine the timescale of any variability. In § 2 we present the results of our observational campaign, in § 3 we present models for the observed photometric variability, and we summarize our findings in § 4.

## 2. OBSERVATIONS

Data for HH 30 IRS (R.A. $= 04^h31^m37\overset{s}{.}5$, decl. $= 18°12'26''\!.0$; $V \sim 19.5$, $I \sim 17.3$; Mundt & Fried 1983) were obtained with the 1.2 m telescope at the F. L. Whipple Observatory (FLWO), using the "4Shooter" CCD mosaic (A. H. Szentgyorgyi et al. 2000, in preparation) with four thinned, back side–illuminated, antireflection-coated Loral $2048^2$ CCDs. The camera has a pixel scale of $0''\!.335$ pixel$^{-1}$ and field of view of roughly $11'\!.5$ for each chip. The data were taken in the $2 \times 2$ CCD binning mode. To obtain multiwavelength variability information we used *VRI* filters from the FLWO "Harris set." We obtained data (see Fig. 1) between 1999 September 7 and 2000 February 28, usually consisting of up to three sets of 300, 180, and 180 s *VRI* exposures. In total we have 24 useful images of HH 30 IRS in the *V* band and 27 useful images in each of the *RI* bands, spanning about 174 days. The seeing ranged from FWHM $= 1''\!.3$ to about $4''\!.0$. The *VRI* data can be accessed from ANONYMOUS FTP.[6]

Preliminary processing of the CCD frames was done with the standard routines in the IRAF-CCDPROC package.[7] Photometric variability was determined using two separate techniques: aperture photometry and point-spread function (PSF) fitting. PSF fitting was done using the photometric pipeline of the project DIRECT (Kałużny et al. 1998; Stanek et al. 1998),

Fig. 1.—HH 30 IRS *VRI* photometric variability

based on the DAOPHOT/ALLSTAR photometry package (Stetson 1987, 1991). The differential light curves obtained by both methods agreed well, which was reassuring considering that the HH 30 IRS nebulosity is somewhat resolved in our images. As a further check, we saw no correlation between the derived photometric changes and the seeing or sky brightness.

The resulting *VRI* differential light curves are shown in Figure 1 and are adjusted so the faintest measurement in each band corresponds to $\Delta$mag = 0. The HH 30 IRS nebulosity was observed to vary in brightness over timescales of a few days by $\Delta V \sim 1.4$ mag, $\Delta R \sim 1.0$ mag, and $\Delta I \sim 1.1$ mag. The changes in brightness are very well correlated between the three photometric bands. There are hints of periodicity with the rise and fall at the start of our observations and again around HJD 1,570 in Figure 1. Independently for each band, we searched for periodicity using a variant of the Lafler & Kinman (1965) string length technique, proposed by Stetson (1996), and also the Lomb (1976) normalized periodogram method. The strongest signals in our periodogram techniques were found at 19.8 days (97% probability) and 11.6 days (95% probability). An 11.6 day period is more typical of T Tauri stars, and further monitoring of HH 30 IRS will possibly yield a more reliable period. We emphasize that this period detection is very tentative given the present data, and we encourage follow-up observations to confirm or refute our finding.

Photometric variability in excess of 2 mag may be obtained by hot spots on the stellar surface (e.g., Mahdavi & Kenyon 1998). Hot spots produce larger photometric variability at shorter wavelengths due to the increased spot/star luminosity ratio. Our observations show that $\Delta V > \Delta I$ but $\Delta R < \Delta I$. The apparent inconsistency of the *R*-band variability may be attributed to contamination from strong H$\alpha$ and [S II] emission associated with HH 30 IRS's jet (Burrows et al. 1996). Bouvier et al. (1999) discounted a hot spot model for AA Tau because they did not detect any color variations ($\Delta$mag $\sim 1.4$ in all *BVRI* bands). Our HH 30 IRS data do show color variations, and in the next section we investigate hot spot models for HH 30 IRS and restrict our simulations to the *V* and *I* bands

because of the likely contamination of the *R*-band observations by jet emission.

### 3. MODELS

The large variability we observe may occur for a model with two diametrically opposed hot spots when the second spot is occulted (either by the star or the circumstellar disk), and the observed spot is seen directly at maximum light and is obscured by the star at minimum light. However, for the high inclination of HH 30 IRS ($i > 80°$; Burrows et al. 1996) we see only a scattered light nebula and do not see the star directly. For a model with two diametrically opposed hot spots, we found that at high inclinations the photometric variability was only around 0.2 mag (Wood & Whitney 1998). As one spot rotates behind the star, the second spot rotates to the front, yielding the small amplitude variability. In addition, because we are detecting only scattered light, we always see some reflected light from the hot spots, yielding small variations in the total intensity.

The fact that we are viewing scattered light makes it impossible for us to apply inversion techniques to determine spot parameters (e.g., Bouvier et al. 1993; Vrba, Herbst, & Booth 1988), since the light curves are sensitive not only to the star and spot parameters but also to the disk structure and circumstellar dust properties. The new Wide Field Planetary Camera 2 observations presented by Stapelfeldt et al. (1999a) and the large variability present in Figure 1 suggest that one hot spot dominates the nebular and photometric variability. We now construct single–hot spot models for HH 30 IRS.

HH 30 IRS has been modeled by Burrows et al. (1996) and Wood et al. (1998) with a flared disk geometry:

$$\rho = \rho_0 \exp - \frac{1}{2} [z/h(\varpi)]^2/\varpi^\alpha, \qquad (1)$$

where $\varpi$ is the radial coordinate in the disk midplane and the scale height increases with radius, $h = h_0 (\varpi/R_*)^\beta$. Following Burrows et al. (1996) and Wood et al. (1998) we adopt $\beta = 9/8$, $\alpha = 15/8$, $h_0 = 0.05 R_*$ [giving $h(100$ AU$) = 15$ AU], and a disk mass of $2.5 \times 10^{-4}$ $M_\odot$. We construct scattered light models using our Monte Carlo radiation transfer code (Whitney & Hartmann 1992; Wood & Whitney 1998; Stassun & Wood 1999) and assume there is one circular hot spot of radius $\theta_s$ at latitude $\phi_s$ on the stellar surface. The relative number of photons released from the spot and star is

$$\frac{N_s}{N_*} = \frac{1 - \cos \theta_s}{1 + \cos \theta_s} \frac{B_\lambda(T_s)}{B_\lambda(T_*)}, \qquad (2)$$

where we assume that the luminosities of the star and spot are Planck functions at the spot ($T_s$) and stellar ($T_*$) temperatures.

Figure 2 shows the simulated *V*- and *I*-band photometric variability for $\theta_s = 20°$, $\phi_s = 65°$, $T_s = 10^4$ K, and $T_* = 3800$ K (Wood & Whitney 1998; Stapelfeldt et al. 1999a). We assumed that the circumstellar dust can be characterized by a Kim, Martin, & Hendry (1994, hereafter KMH) size distribution, typical of grains in the interstellar medium. For KMH grains, the *V*- and *I*-band dust parameters (opacity, albedo, peak polarization, and asymmetry parameter in the Heyney-Greenstein scattering phase function) are displayed in Table 1.

Viewing this model at low inclinations, we can easily obtain $\Delta V \sim 1.5$ mag. However, at $i = 82°$, we cannot reproduce the observed large amplitude variability—we see only scattered light and always detect reflected light from the hot spot, irre-
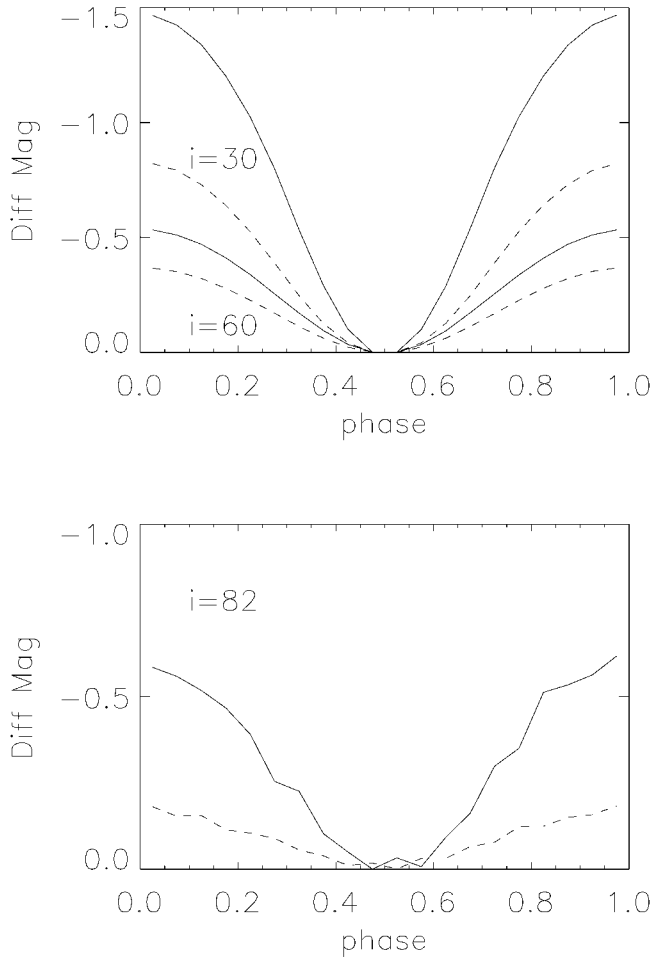

Fig. 2.—Single-spot model with KMH grains, $T_s = 10^4$ K, $T_* = 3800$ K, $\theta_s = 20°$, and $\phi_s = 65°$. The upper panel shows the variability for viewing angles of $i = 30°$ and $i = 60°$; the lower panel shows the variability for the more edge-on viewing angle $i = 82°$ appropriate to HH 30 IRS. The solid line is the $V$ simulation, and the dashed line is the $I$ simulation.

spective of rotational phase. Therefore, the amplitude of variability is smaller ($\Delta V \sim 0.5$ mag, $\Delta I \sim 0.3$ mag) than when we see the star directly. One way of increasing the variability is to change the spot size and temperature. Alternatively, if the forward beaming of the scattered light is increased (increasing the asymmetry parameter $g$), we will see less scattered light from the spot at minimum light when it is occulted by the star. Such an increase in the asymmetry parameter, indicative of large grains in the disk, was found by Burrows et al. (1996). Other modeling efforts have also found evidence for larger, more forward-throwing grains in protostellar environments (e.g., Lucas & Roche 1998). We have therefore constructed models with larger, more forward-throwing grains (see parameters in Table 1). This population of grains was used by A. Cotera et al. (2000, in preparation) and B. A. Whitney & M. J. Wolff (2000, in preparation) to model multiwavelength *HST* images of HH 30 IRS. The dust grains are homogeneous spheres composed of either amorphous carbon (BE1; Rouleau & Martin 1991) or revised astronomical silicate (Weingartner & Draine 2000). The size distribution for each component is specified using a power law with exponential decay [i.e., $a^{-p} \exp{(-a/a_c)}$] with a cross section weighted average radius (summed over both components) of 0.092 $\mu$m. The relative numbers of each grain type are such that the dust completely

TABLE 1
PARAMETERS FOR DUST GRAINS

| Wave Band | $\kappa$ (cm$^2$ g$^{-1}$) | $a$ | $g$ | $P$ |
|---|---|---|---|---|
| $V$ (KMH) ...... | 220 | 0.54 | 0.44 | 0.43 |
| $I$ (KMH) ....... | 105 | 0.49 | 0.29 | 0.70 |
| $V$ (large) ....... | 174 | 0.47 | 0.61 | 0.38 |
| $I$ (large) ....... | 134 | 0.49 | 0.58 | 0.34 |

consumes slightly "supersolar" abundances in carbon and silicate: 400 parts per million for C/H and 40 parts per million for Si/H. We refer the reader to B. A. Whitney & M. J. Wolff (2000, in preparation) for a more detailed discussion of the dust model.

With the larger grains, the amplitude of the variability is unaffected at low inclinations because the direct starlight is much brighter than the scattered light. For $i = 82°$, we found larger variability ($\Delta V \sim 1$ mag, $\Delta I \sim 0.5$ mag) than for the simulation using KMH grains as a result of the increased beaming of the scattered light by the forward-throwing grains.

Increasing the phase function asymmetry through larger grains increases the photometric variability, but it is still less than observed. Therefore, we have investigated other models that have larger spot/star luminosity ratios and different spot parameters. Figure 3 shows a simulation in which we obtain $\Delta V \sim 1.45$ mag and $\Delta I \sim 1.05$ mag, in agreement with our observations. This simulation has $T_s = 10^4$ K, $T_* = 3000$ K, $\theta_s = 20°$, and $\phi_s = 60°$. We can obtain the same amplitude of variability with a model that has $T_* = 3800$ K and $T_s = 2 \times 10^4$ K. As the central star in the HH 30 IRS system is not observed directly, its effective temperature is somewhat uncertain and may be cooler than the $T_* = 3800$ K, M0 spectral type determined by Kenyon et al. (1998). The large spot/star luminosity, required to match our observations, could result in considerable veiling allowing for a later spectral type (see Ken-

Fig. 3.—Single-spot model with larger, more forward-throwing grains and a larger spot/star luminosity ratio, $T_s = 10^4$ K, $T_* = 3000$ K, $\theta_s = 20°$, $\phi_s = 60°$. The solid line is the $V$ simulation, and the dashed line is the $I$ simulation.

yon et al. 1998). The spot size and latitude may be constrained through detailed modeling of time series images of the scattered light disk (Stapelfeldt et al. 1999a).

## 4. SUMMARY

We have presented *VRI* photometric observations of HH 30 IRS that show it is highly variable over timescales of a few days ($\Delta V \sim 1.4$ mag, $\Delta R \sim 1.0$ mag, $\Delta I \sim 1.1$ mag), with hints of periodicity at 11.6 or 19.8 days. This contrasts with the recent work of Stapelfeldt et al. (1999b), whose *HST* observations suggest a characteristic timescale on the order of 15 yr, possibly related to inhomogeneities in the disk. The much shorter timescale variability in our data indicates a stellar origin for the photometric variability we observe. High-resolution imaging is required to determine whether the variability we observe is related to the morphological variations in the scattered light images.

Comparing our findings to classical T Tauri stars, HH 30 IRS's variability is among the largest yet reported. We have modeled the variability in the context of the magnetospheric accretion model with a single hot spot on the stellar surface. The large variability requires a large spot/star luminosity ratio and that the circumstellar grains are larger and more forward-throwing than interstellar grains. Variability due to accretion hot spots is often stochastic (e.g., Herbst et al. 1994), and while our modeling has adopted a single stable hot spot, further observations are required to better sample the light curve and determine changes in the spot sizes and temperatures. Our modeling of the circumstellar dust is consistent with many other studies that are providing evidence for grain growth in dense environments of T Tauri stars.

While our observations and modeling support the magnetic accretion hypothesis for HH 30 IRS, alternative sources of the variability may be orbiting dust clouds, inhomogeneities in the disk structure close to the star, a binary star, and stellar flares. Further monitoring of HH 30 IRS with sampling on the order of days will yield further insight into this system. If the variability is due to magnetic accretion, there will be specific time sequence variations of the photometry, polarimetry, and morphology of the scattered light disk due to illumination by hot spots. Even if the accretion is stochastic, there will be specific correlations between the photometry and polarimetry (Stassun & Wood 1999, Fig. 7). Rotational modulation will manifest itself in high-resolution imaging studies through asymmetric brightening of scattered light images (Wood & Whitney 1998; Stapelfeldt et al. 1999a). Lower resolution imaging should still be able to detect the asymmetric brightening via shifting of the photometric centroid of the system as pointed out by Stapelfeldt et al. (1999a).
