ABSTRACT
The unusual spectral energy distribution (SED) of the classical T Tauri star GM Aurigae provides evidence for the presence of an inner disc hole extending to several au. Using a combination of hydrodynamical simulations and Monte Carlo radiative transport, we investigate whether the observed SED is consistent with the inner hole being created and maintained by an orbiting planet. We show that an \( \sim 2\) M\(_J\) planet, orbiting at 2.5 au in a disc with mass 0.047 M\(_\odot\) and radius 300 au, provides a good match both to the SED and to CO observations which constrain the velocity field in the disc. A range of planet masses is allowed by current data, but could in principle be distinguished with further observations between 3 and \( \sim 20\) \( \mu \)m. Future high-precision astrometric instruments should also be able to detect the motion of the central star caused by an orbiting Jupiter-mass planet. We argue that the small number of T Tauri stars with SEDs resembling that of GM Aur is broadly consistent with the expected statistics of embedded migrating planets.

Key words: accretion, accretion discs – radiative transfer – scattering – planetary systems: protoplanetary discs – stars: pre-main-sequence – dust, extinction.

1 INTRODUCTION
The detection of extrasolar planets and planetary systems (e.g. Mayor & Queloz 1995) has invigorated studies of planetary formation (Lissauer 1993; Bos 1998, 2000), migration (e.g. Lin & Papaloizou 1986; Lin, Bodenheimer & Richardson 1996; Trilling et al. 1998; Nelson et al. 2000b) and interaction with a protoplanetary disc (Lin & Papaloizou 1979a,b; Artymowicz & Lubow 1994). Recent theoretical work has investigated mechanisms for halting planetary migration and explaining the statistical distribution of the orbital radii of extrasolar planets (Armitage et al. 2002; Kuchner & Lecar 2002; Trilling, Lunine & Benz 2002). Theoretical models for the interactions of (proto) planets with a protoplanetary disc show that large low-density regions (gaps) can be created within the disc (Lin & Papaloizou 1979a,b; Artymowicz & Lubow 1994). The detection of these gaps would provide strong support for planetary formation theories, but current observations do not have the spatial resolution to image directly the au-sized gaps that are predicted. Future instrumentation, such as Atacama Large Millimeter Array (ALMA), may allow direct detection of gaps (Wolf et al. 2002), but for now we are restricted to spectral techniques for inferring the presence of disc gaps.

Spectral energy distributions (SEDs) from protoplanetary discs arise from the thermal reprocessing of starlight and dissipation of viscous accretion luminosity (Lynden-Bell & Pringle 1974; Adams, Lada & Shu 1987; Kenyon & Hartmann 1987). The resulting SEDs display characteristic infrared excesses that are sensitive to the size, shape and mass of the disc. Disc gaps may manifest themselves in SEDs by removing material that would normally have contributed to the SED at a given wavelength: gaps close to the star result in smaller than usual near-infrared excesses, while gaps at large disc radii will cause distortions to the SED at longer wavelengths (Beckwith 1999). The classical T Tauri stars GM Aur and TW Hya have SEDs that indicate the inner regions of their discs have been cleared of material out to around 4 au from the central stars (Koerner, Sargent & Beckwith 1993; Chiang & Goldreich 1999; Calvet et al. 2002; Schneider et al. 2003).

There are a number of possible mechanisms for clearing such gaps. Photo-evaporation by ultraviolet radiation, either from the central star or from surrounding radiation, can produce a disc wind at radii where the sound speed exceeds the escape velocity (Clarke, Gendrin & Sotomayor 2001). The inner regions of the disc will

⋆E-mail: wkmr@st-andrews.ac.uk

© 2003 RAS
then be cleared on a viscous time-scale once the wind mass-loss rate is comparable to the accretion rate. This, however, generally requires an accretion rate two orders of magnitude lower than the $10^{-8} \, M_{\odot} \, yr^{-1}$ accretion rate expected for GM Aur (Gullbring et al. 1998). Clarke et al. (2001) also assumed a constant ionizing flux. Matsuyama et al. (2003) showed that the clearing of the inner disc is even less likely if the decrease in ionizing flux with decreasing accretion rate is included in the calculation. Nelson, Benz & Ruzmaikina (2000a) also suggested that viscous dissipation and the dissipation of gravitational instabilities may increase the mid-plane temperature of the inner regions of the disc to above the grain destruction temperature. This would then manifest itself as a reduction in the flux of radiation with wavelengths between a few and 10 μm. Their simulation, however, assumed a disc luminosity (0.5 L⊙) an order of magnitude greater than that calculated by Gullbring et al. (1998) for GM Aur (0.071 L⊙).

It has been suggested (Calvet et al. 2002) that the inner regions of the disc of TW Hya could be cleared by tidal interactions with an embedded planet (Lin & Papaloizou 1979a,b). In this paper we consider whether the gap in the disc of GM Aur could be formed in the same way. We use a dynamical model of an approximately Jupiter-mass planet in a protoplanetary accretion disc, with parameters appropriate for GM Aur (e.g. Koerner et al. 1993; Simon et al. 2000; Schneider et al. 2003), to investigate whether the resulting disc structure can reproduce the observed SED. We also consider other planet masses to test whether the SED can be used to constrain the planet mass. Estimates for the age of GM Aur vary from ∼1.5 Myr (Beckwith et al. 1990; Siess et al. 1999) to ∼10 Myr (Simon & Prato 1995; Hartmann 2003). There has therefore been sufficient time for an embedded planet to have formed via core accretion (Lissauer 1993) or via gravitational collapse (Boss 1998, 2000). The observation of a much younger system (e.g. <1 Myr) with an SED signature indicating the presence of a disc gap would, if the gap could be shown to be due to the presence of an embedded planet, suggest either that core accretion occurs on a much shorter time-scale than expected or that planet formation can occur via an alternative mechanism such as gravitational collapse. In Section 2 we describe and present the results of our dynamical simulations; in Section 3 we compare model SEDs with the observed SED of GM Aur, and in Section 4 we summarize our results.

2 DYNAMICAL SIMULATIONS

2.1 Dynamical model and initial conditions

The simulations presented here were performed using smoothed particle hydrodynamics (SPH), a Lagrangian hydrodynamics code (e.g. Benz 1990; Monaghan 1992). We initially assume that a planet with mass $M_p = 1.7 \, M_J$ orbits a star, with mass $M_\ast = 0.85 \, M_{\odot}$, at a radius of $r_p = 2.5 \, au$. Both the central star and planet are modelled as point masses on to which gas particles can accrete if they approach to within the sink radius (Bate, Bonnell & Price 1995). The planet orbits within a circumstellar disc of mass $M_{\text{disc}} = 0.047 \, M_{\odot}$, modelled using 300 000 SPH gas particles distributed such as to give a surface density profile of $\Sigma \propto r^{-1}$ (D’Alessio et al. 1998). The disc extends from $r_{in} = 0.25 \, au$ to $r_{out} = 300 \, au$. The disc temperature varies as $T \propto r^{-1/2}$, as expected for discs heated by starlight (D’Alessio et al. 1998), and we assume hydrostatic equilibrium in the vertical direction, giving a central density profile of $\rho \propto r^{-2.25}$. For the SPH simulation, the disc is assumed to be locally isothermal and the above temperature profile is maintained throughout the simulation. The parameters chosen are appropriate for GM Aur based on calculations of the stellar mass (Simon et al. 2000) and the disc mass and size (Schneider et al. 2003).

The vertical scaleheight, $H$, of the disc is given by $H^2 = c_s^2 r^3 / GM_\ast$, where $c_s$ is the local sound speed, $r$ is the radius, $G$ is the gravitational constant, and $M_\ast$ is the stellar mass. The temperature is normalized such as to give a scaleheight of 10.5 au at 100 au. The scaleheight at 2.5 au is then 0.1 au, giving an $H/r$ value of 0.04. This choice of scaleheight was based on an SED model using an analytic disc geometry and is similar to that obtained by Schneider et al. (2003). In using the above form for the scaleheight, we assume that the dust has the same scaleheight as the gas. Although this may not necessarily be the case, the need to use a dust scaleheight that has the same form as a standard equilibrium disc (e.g. Pringle 1981) would seem to make this a reasonable assumption.

Using 300 000 SPH particles, the vertical profile of the disc can be modelled accurately within ∼3 scaleheights of the disc mid-plane. For higher altitudes, the density is calculated analytically using (e.g. Pringle 1981)

$$\rho(z, r) = \rho_i(r) \exp(-z^2/2H^2).$$

where $z$ is the height above the disc mid-plane, and $\rho_i(r)$ is the central density a distance $r$ from the central star, determined using the dynamical model. Very little mass is contained in these regions of the disc and it is hence unimportant for the dynamical calculation. It is, however, extremely important for calculating the radiative transfer through the disc (see D’Alessio et al. 1998).

Self-gravity is included in the calculation, and both the point masses and the gas use a tree to calculate gravitational forces (Benz 1990). The inclusion of self-gravity means that the central star and planet are both free to move under the gravitational influence of the disc. A great saving in computational time is obtained by using individual, particle time-steps (Navarro & White 1993; Bate et al. 1995) which are limited by the Courant condition and a force condition (Benz 1990).

2.2 Planet–disc interactions

A planet orbiting within a circumstellar disc will tidally interact with the disc. Disc material exterior to the planet will gain angular momentum from the planet and will move to larger radii, while material interior to the planet will lose angular momentum and move to smaller radii (Lin & Papaloizou 1979a,b; Artymowicz & Lubow 1994). Viscous processes within the disc will tend to act against the tidal forces, and the formation of a gap will depend on the tidal forces overcoming these viscous processes (Lin & Papaloizou 1979a). This depends on the relative magnitudes of the mass ratio of the planet and the star, $q$, and the Reynolds number within the disc, $R$. If $q > R^{-1}$ a gap will form, while if $q^2 > R^{-1}$ the disc will be truncated at the outer Lindblad resonance. The Reynolds number is given by $\Omega r^2 / \nu$, where $\Omega$ is the angular frequency, $r$ is the radius and $\nu$ is the turbulent viscosity in the disc, generally described as an alpha viscosity (Shakura & Sunyaev 1973).

For the initial simulation ($M_p = 1.7 \, M_J$, $M_{\text{disc}} = 0.047 \, M_{\odot}$) considered here, $q = 0.002$, and the Reynolds number, determined from the artificial viscosity included in the code (Murray 1996), is ~20 000. Therefore $q > R^{-1}$ but $q^2 < R^{-1}$. A gap should form with the gap edge at the outer Lindblad resonance located, for a planet orbiting at 2.5 au, at a radius $r = 4 \, au$. However, for the mass ratio and Reynolds number in this initial simulation, the disc should not be strongly truncated at the outer Lindblad resonance. The Lindblad resonance can be determined from $\Omega(r) = \omega m/(1 + m)$, where
Accretion on to the central star and the orbiting planet continues throughout the simulation despite the formation of the gap, consistent with simulations performed by Artymowicz & Lubow (1996).

3 Radiation Transfer Models

We calculate the SED for our simulations using the Monte Carlo radiative equilibrium technique of Bjorkman & Wood (2001). The output of our radiative transfer simulation is the disc temperature structure and the emergent SED. The disc heating is assumed to be from starlight and the Monte Carlo ‘photons’ are tracked within a two-dimensional grid in \( r \) and \( \theta \). Our radiation transfer code calculates disc temperature and does not assume a vertically isothermal structure as in the SPH simulation. The input stellar spectrum is a 4000-K, \( \log g = 3.5 \) Kurucz model atmosphere (Kurucz 1994) and the stellar radius \( R_\ast \) is taken to be 1.75 \( R_\odot \). The circumstellar dust opacity is taken to be that described in Wood et al. (2002) which fits the HH 30 IRS SED and was also used to fit the GM Aur SED (Schneider et al. 2003). The dust model has a shallower wavelength-dependent opacity than ‘standard’ interstellar medium (ISM) dust (e.g. Mathis, Rumpl & Nordsieck 1977) and a larger grain size as inferred for many other classical T Tauri stars (e.g. Beckwith et al. 1990; Beckwith & Sargent 1991).

We find that the dearth of near-infrared excess in the SED of GM Aur cannot be explained by a dust composition different from that used here. Using an ISM mixture and a disc without a substantial gap still results in a near-infrared excess not observed in GM Aur. Our results are also in agreement with the Calvet et al. (2002) modelling of TW Hya. In their model they do use different dust types in the inner and outer disc, but still require a very low-density inner disc to reproduce the near-infrared emission observed in TW Hya. Further, ISM grains yield too steep a slope to the submillimetre SED (see also Beckwith & Sargent 1991). We therefore conclude that the dearth of near-infrared excess emission from GM Aur can only be explained by an evacuated (low density) inner region.

Circumstellar discs absorb and reprocess stellar photons in a layer which, depending on the disc optical depth, can lie 4–5 scaleheights above the disc mid-plane (D’Alessio et al. 1999). Our SPH simulations cannot resolve this low-density material, so to provide a density grid for our radiation transfer simulations we have extrapolated the density, using equation (1), to large heights above the disc mid-plane. The density calculated from the SPH simulations was

The central star has increased from its initial mass of 0.85 \( M_\odot \) to a mass of 0.85019 \( M_\odot \) after 1820 yr, while the orbiting planet has increased from \( 1.7 \times 10^{-3} \) to \( 1.88 \times 10^{-3} \) \( M_\odot \) in the same time-period. The accretion rates at the end of the simulation (averaged over the last 100 yr) were ~5 \( \times 10^{-8} \) and \( 1 \times 10^{-8} \) \( M_\odot \) yr\(^{-1}\) for the central star and orbiting planet respectively. An accurate calculation of the accretion rate in our simulation is limited by the mass resolution, since each SPH particle has a mass of \( 1.6 \times 10^{-7} \) \( M_\odot \), and by our simplistic accretion process. We do not include the rotating magnetosphere of the T Tauri star which is likely to truncate the disc at the corotation radius and force the accretion flow to follow the stellar magnetic field lines (Ghosh & Lamb 1978). The accretion rate from the model is, however, similar to that expected for GM Aur (Gullbring et al. 1998). That mass is flowing through the gap and accreting on to the central star and planet is also consistent with other simulations (Artymowicz & Lubow 1996; Lubow, Siebert & Artymowicz 1999).

The disc velocities also remain very close to Keplerian despite the presence of an orbiting planet that perturbs the potential. This is consistent with CO observations (Koerner et al. 1993; Dutrey et al. 1998) which suggest that GM Aur is surrounded by a Keplerian circumstellar disc inclined at \( \sim 50^\circ \).
azimuthally averaged and then interpolated on to a two-dimensional grid in $r$ and $\theta$. The grid has 100 cells for $0.25 \leq r \leq 300$ au spaced proportional to $r^3$ and 400 cells linearly spaced for $0 \leq \theta \leq \pi$. This gridding allows us to resolve the SPH density adequately for our SED calculations.

### 3.1 GM Aur SED

Fig. 2 shows the GM Aur SED data. The dotted line shows the input model atmosphere, and the open squares are data points obtained using various instruments (e.g. Cohen & Kuhl 1997; Beckwith & Sargent 1991; Weaver & Jones 1992; Kenyon & Hartmann 1995). The solid line shows the SED calculated using the azimuthally averaged SPH density as input to the Monte Carlo radiation transfer calculation. The SPH simulation was run for 450 orbits of the 1.7-M$_J$ planet at 2.5 au (1820 yr), giving sufficient time for the density profile to reach a steady state. The disc structure is also approximately azimuthally symmetric since the viscous time-scale is significantly greater than the orbital period of the planet. The inclination of the disc was taken to be 50°, consistent with the value of 54° ± 5° determined by Dutrey et al. (1998), and with the recent scattered light models of Schneider et al. (2003). The model SED provides a good fit to the observations, particularly the lack of near-infrared excess and the level and slope of the long-wavelength continuum. The dashed line in Fig. 2 is the SED for an equivalent disc in which a gap is not present and in which the inner edge of the disc is taken to be at 7 stellar radii. Comparison between the solid line and dashed line clearly shows that the effect of the disc clearing is to reduce the excess emission at short wavelengths ($2-10$ $\mu$m) and slightly increase the excess at longer wavelengths ($10-30$ $\mu$m).

This is a consequence of the stellar flux being reprocessed at the disc edge. In the simulation with $R_{\text{min}} = 7 R_\ast$ (dashed line in Fig. 2), stellar photons are reprocessed in high-temperature ($>1000$ K) regions of the disc, giving a near-infrared excess. When a gap is present, the photons are reprocessed further out in the disc where the temperature is lower, decreasing the near-infrared flux and increasing the flux at longer wavelengths. A fit to the data is only possible if the gap extends all the way to the inner disc boundary. If the planet has only had sufficient time to clear a ring of material, leaving the inner disc almost unchanged, this inner material should remain hot, resulting in $2$- and $3$-$\mu$m fluxes similar to that for the dashed line in Fig. 2, and higher than that observed for GM Aur (open squares).

### 3.2 Companion (planet) mass and viscosity

Although we are able to reproduce the observed SED with a 1.7-M$_J$ planet orbiting at 2.5 au, the exact form of the density profile depends on the relationship between the mass ratio, $q$, and the disc Reynolds number, $\mathcal{R}$. A weakness of SPH is the difficulty in determining exactly the viscosity and hence Reynolds number. In light of this, we have performed a number of additional simulations considering substellar companions (planets) of various masses, each of which was run for at least 250 orbits of the companion around the central star ($>1000$ yr). In these simulations the disc was modelled between 0.25 and 100 au using 150 000 SPH particles with a surface density profile such that the total disc mass would be $0.047 M_\odot$ were the disc extended to 300 au. Using 150 000 SPH particles to simulate the inner 100 au of the disc should give approximately the same resolution as the 300 000 particles used to simulate the disc out to 300 au. The Reynolds number in the simulations using 150 000 SPH particles should therefore be very similar to the Reynolds number in a 300 000-particle simulation (Murray 1996). The companion masses considered for these additional simulations were 0.085, 21 and 43 M$_J$. In simulating companions with relatively large masses (21 and 43 M$_J$) we are not necessarily suggesting that one would expect to observe substellar companions with such masses, but simply illustrating how the SED can vary with mass. Strictly speaking, such massive objects would generally be regarded as brown dwarfs, and we therefore refer to the 21- and 43-M$_J$ companions as substellar objects rather than planets.

The process of star formation is known preferentially to produce binary stellar systems rather than single stars (Duquennoy & Mayor 1991). On the main sequence, however, the mass ratio of close binaries is rarely so extreme as to pair a solar-mass star with a brown dwarf (Marcy & Butler 2000; Halbwachs et al. 2000). If this trend also exists during the pre-main-sequence phase, one would expect disc-embedded planetary mass objects to be more common than embedded close brown dwarfs. The formation mechanism of close binaries is, however, unclear with some simulations (Bate, Bonnell & Bromm 2002) suggesting substantial evolution of binary orbital parameters while a disc is present. The possibility of observing substellar-mass companions at this early stage could therefore be an important test of different binary formation models.

The Reynolds number, $\mathcal{R}$, in the disc is calculated to be $\sim 20 000$. The 0.085- and 1.7-M$_J$ planets therefore have $q > \mathcal{R}^{-1}$ but $q^2 < \mathcal{R}^{-1}$, while the 21- and 43-M$_J$ substellar objects have $q > \mathcal{R}^{-1}$ and $q^2 > \mathcal{R}^{-1}$. The two planets (0.085 and 1.7 M$_J$) should therefore produce gaps that are not strongly truncated at the outer Lindblad resonance, while the two substellar objects (21 and 43 M$_J$) should truncate the disc strongly at the outer Lindblad resonance (Lin & Papaloizou 1979a; Syer & Clarke 1995). For a Reynolds number larger than used here, a planetary-mass companion (<10 M$_J$) would satisfy easily the latter condition ($q > \mathcal{R}^{-1}$ and $q^2 > \mathcal{R}^{-1}$). The results that we obtain for the companions referred to as substellar objects would therefore also be applicable to planetary-mass objects in a disc with a Reynolds number larger than in the simulation presented here.

Figure 2. The SED of GM Aur (squares), our model viewed at $i = 50^\circ$ (solid line) and the input stellar spectrum (dotted line). The dashed line shows the SED calculated in the absence of a gap with the disc extending in to 7 stellar radii. The presence of a gap (solid line) clearly reduces the near-infrared flux and enhances the flux at slightly longer wavelengths.

The protoplanetary disc of GM Aurigae

Figure 3. Azimuthally averaged mid-plane density profiles for substellar objects (planets) with masses of 0.085 (dotted line), 1.7 (solid line), 21 (dash–dotted line) and 50 $M_J$ (dashed line). The two higher mass objects truncate the disc more strongly at the outer Lindblad resonance than the two lower mass planets.

Fig. 3 shows the azimuthally averaged mid-plane densities for the three additional masses together with the azimuthally averaged mid-plane density profile for the 1.7-$M_J$ planet, between radii of 0.25 and 25 au. As expected, the 0.085- and 1.7-$M_J$ planets produce gaps with soft edges, while the 21- and 43-$M_J$ objects truncate the disc strongly at the outer Lindblad resonance. The position of the gap edge varies slightly for the different masses, but in all cases is close to the outer Lindblad resonance at $\sim 4$ au.

Fig. 4 shows the SEDs calculated using the azimuthally averaged density profiles for the four masses as input to the radiation transfer calculation. Since the simulations considering masses of 0.085, 21 and 43 $M_J$ were only performed out to 100 au, the density profiles were extrapolated to 300 au. The solid and dotted lines are for the 1.7- and 0.085-$M_J$ planets, while the dashed and dash–dotted lines are for the 43- and 21-$M_J$ substellar objects. The SEDs for the 1.7- and 0.085-$M_J$ planets are very similar, as are the SEDs for the two substellar objects (21 and 43 $M_J$), which are, in fact, very difficult to separate. Fig. 5 shows a detailed view of the computed SEDs between 5 and 200 $\mu$m with the line styles the same as in Fig. 4. Fig. 5 also shows $\pm 25$ per cent error bars on the data points (open squares). This choice of error was based on worst-case 1$\sigma$ error estimates (Cohen & Kuhi 1979; Weaver & Jones 1992; Kenyon & Hartmann 1995). Apart from the SED flux at 12 $\mu$m due to the 0.085-$M_J$ planet (dotted line) being slightly higher than that observed, the SEDs computed from the density profiles fit the 2-, 3- and 12-$\mu$m data points well. The flux between 3 and 12 $\mu$m varies quite considerably for the different masses, suggesting that more observations in this wavelength range could allow for the determination of the companion mass or, since the Reynolds number in the disc is unlikely to be accurately known, the relationship between the mass ratio and the Reynolds number. The SEDs arising from the 21- and 43-$M_J$ substellar objects also have a flux at 25 $\mu$m that is considerably higher than that observed. Although not definitive, this may suggest that if the GM Aur SED is due to an embedded companion (planet) orbiting at $\sim 2.5$ au, the mass must be such as to produce a gap that is not strongly truncated at the outer Lindblad resonance, i.e. $q > R^{-1}$ but $q^2 < R^{-1}$. This also appears to be the case for TW Hya as Calvet et al. (2002) require low-density material within 4 au to fit the 2–10 $\mu$m SED flux.

At the distance of GM Aur (140 pc), a few Jupiter-mass planet orbiting at 2.5 au will produce a ‘wobble’ in the central star with an angular displacement of $\sim 0.1$ milliarcsec, and a period of 4 yr. Future high-precision astrometric instruments should be sufficiently sensitive to make such an observation. Observations of this kind have been suggested both for detecting the presence of embedded...
Additional simulations of companions (planets) with masses of 0.085, 21 and 43 M\(_J\) have also been performed. The structure of the resulting gaps depends on the relationship between the mass ratio and the Reynolds number in the disc. For the Reynolds number in our simulations, the two planets (0.085 and 1.7 M\(_J\)) produce gaps with relatively soft edges, while the two substellar objects (21 and 43 M\(_J\)) truncate the disc strongly at the outer Lindblad resonance (\(\sim 4\) au). As with the 1.7-M\(_J\) planet, the SED computed using the density profile due to the 0.085-M\(_J\) planet fits the data points extremely well. The SEDs computed using the density profiles due to the two substellar objects (21 and 43 M\(_J\)) fit most data points well but have quite a significant excess at 25 \(\mu\)m. Although not definitive, this may suggest that the mass must be such as to produce a gap that is not strongly truncated at the outer Lindblad resonance. Further observations between 3 and 20 \(\mu\)m, where there is a considerable difference in the computed SEDs, but currently no data points, will be needed to determine if this is indeed the case. Future SIRTF observations will provide the required measurements to test our predictions.

Since the density profile depends on the relationship between the mass ratio and the Reynolds number, additional information would be required to determine the actual planet mass. A few-M\(_J\) planet orbiting at 2.5 au will produce a ‘wobble’ in the central star, at the distance of GM Aur (140 pc), with an angular displacement of \(\sim 0.1\) milliarcsec, and a period of 4 yr. Future high-precision astrometric instruments should be sufficiently sensitive to make such observations. Not only would this establish if a planet is indeed orbiting at \(\sim 2.5\) au, but it should also allow for the determination of the planet mass from which the Reynolds number, and hence the turbulent viscosity, could be estimated.

The transfer of angular momentum between the embedded planet and the disc material is ultimately expected to cause the planet to migrate inwards (Lin & Papaloizou 1986). Simulations (Nelson et al. 2000b) suggest that the migration time-scale is of the order of 10\(^3\) yr for a Jupiter-mass planet starting at 5 au. Since as many as 15 per cent of solar-type stars are expected to have planets within 5 au, that there are only currently two T Tauri stars with SED signatures of close-in massive planets is somewhat surprising. This could reflect the relatively sparse observations in the relevant wavelength range (3–12 \(\mu\)m). Alternatively, fully evacuated inner holes may form in only a fraction of classical T Tauri stars with planets. An annular gap with a sizeable inner disc would lead to less obvious signatures in the SED.
