ABSTRACT

We present optical integral field spectroscopy (IFS) observations of the Mice, a major merger between two massive ($\gtrsim 10^{11} M_{\odot}$) gas-rich spirals NGC 4676A and B, observed between first passage and final coalescence. The spectra provide stellar and gas kinematics, ionised gas properties and stellar population diagnostics, over the full optical extent of both galaxies with ~ 1.6 kpc spatial resolution. The Mice galaxies provide a perfect case study highlighting the importance of IFS data for improving our understanding of local galaxies. The impact of first passage on the kinematics of the stars and gas has been significant, with strong bars likely induced in both galaxies. The barred spiral NGC 4676B exhibits a strong twist in both its stellar and ionised gas disk. The edge-on disk galaxy NGC 4676A appears to be bulge free, with a strong bar causing its “boxy” light profile. On the other hand, the impact of the merger on the stellar populations has been minimal thus far. By combining the IFS data with archival multiwavelength observations we show that star formation induced by the recent close passage has not contributed significantly to the global star formation rate or stellar mass of the galaxies. Both galaxies show bicones of high ionisation gas extending along their minor axes. In NGC 4676A the high gas velocity dispersion and Seyfert-like line ratios at large scaleheight indicate a powerful outflow. Fast shocks ($v_s \sim 350 \text{ km s}^{-1}$) extend to ~ 6.6 kpc above the disk plane. The measured ram pressure ($P/k = 4.8 \times 10^6 \text{ K cm}^{-3}$) and mass outflow rate ($\sim 8 - 20 M_{\odot} \text{ yr}^{-1}$) are similar to superwinds from local ultra-luminous infrared galaxies, although NGC 4676A has only a moderate infrared luminosity of $3 \times 10^{10} L_{\odot}$. Energy beyond that provided by the mechanical energy of the starburst appears to be required to drive the outflow. Finally, we compare the observations to mock kinematic and stellar population maps extracted from a hydrodynamical merger simulation. The models show little enhancement in star formation during and following first passage, in agreement with the observations. We highlight areas where IFS data could help further constrain the models.

Key words. Galaxies: evolution, interactions, stellar content, ISM, Seyfert, kinematics and dynamics, nuclei, bulges; Techniques: Integral Field Spectroscopy

1. Introduction

NGC 4676A and B are members of the original Toomre (1977) sequence of merging galaxies, otherwise known as “the playing mice” (Vorontsov-Vel’iaminov 1958). They are a classic example of a major gas-rich prograde merger, where the roughly equal mass of the progenitors and coincidence of the sense of rotation and orbital motion leads to lengthy tidal tails. NGC 4676A and B (hereafter referred to as the Mice) are one of the earliest stage gas-rich major mergers visible in the nearby Universe, observed close to their apocentre, with N-body simulations and observations agreeing that first passage must have occurred around 170 Myr ago (Barnes 2004; Chien et al. 2007). The system is an outlying member of the Coma cluster, located about 4° or 1.7

virial radii from the centre (Kubo et al. 2007), with a velocity about 350 km s^{-1} from the mean cluster velocity (Burbidge & Burbidge 1961). Figure 1 shows an image of the Mice taken with the Hubble Space Telescope (HST) Advanced Camera for Surveys (ACS).

Massive gas-rich galaxy mergers, of which the Mice are a classic example, may play a key role in the evolution of the galaxy population and in explaining the galaxy demographics in the present day Universe. Within the currently favoured cosmological model of a cold dark matter dominated Universe, structure formation is hierarchical, with small overdensities forming early on and subsequently merging to form larger structures. Galaxies form and evolve within these overdensities, or dark matter halos. When the dark matter halos merge, the galaxies are thought to behave likewise, forming a single more massive sys-

Fig. 1. False colour image $2.4' \times 3.5'$ in size in filters F606W (V, green channel) and F814W (I, red channel) for NGC 4676 using the HST-ACS/WFC (ACS Early Release Observations, Proposal ID 8992, P.I. Ford). Overlaid are V-band contours constructed from the CALIFA integral field datacubes, with the outermost contour at 23 mag/arcsec^2 and contours spaced by $0.45 \text{ mag/arcsec}^2$. The inlaid schematic shows the main kinematical properties of the Mice, as determined from long-slit spectroscopic observations (Burbidge & Burbidge 1961; Stockton 1974), the CALIFA IFS data (Section 4), HI maps and comparisons with N-body simulations (Barnes 2004). Black arrows indicate the direction of rotation of the disks, defined such that the disk of NGC 4676B (SE) is inclined away from the line-of-sight. NGC 4676A is viewed almost exactly edge-on. The thick grey arrow indicates the approximate track that NGC 4676A (NW) has taken relative to NGC 4676B. The pair are observed close to apocentre, with NGC 4676A receding from NGC 4676B at $\sim 160 \text{ km s}^{-1}$ (Section 4).

tem. In order to obtain a complete understanding of how galaxies formed and evolved within this gravitational framework, we need to disentangle the relative importance of the many processes affecting the baryonic material.

By combining high quality spatially resolved optical spectroscopy from the CALIFA survey with archival multiwavelength observations, the aim of this paper is to present a detailed picture of the physical processes induced by the first passage of two massive gas-rich galaxies. In Figure 1 the contours of the reconstructed CALIFA V-band flux are superimposed on the HST image, showing how the large field-of-view of the integral-field unit used by the CALIFA survey allows coverage of the full extent of the bodies of the Mice, including the inter-galaxy region and some of the tidal tails. While the Mice are only one example of an early-stage gas-rich merger, and initial conditions of mergers (galaxy properties, impact parameter, orbital motions etc.)

are expected to lead to a range of final outcomes, this study aims to serve as a reference point for statistical studies of close galaxy pairs, of particular use when combined with other similar case studies (e.g. Engel et al. 2010 [NGC 6240]; Alonso-Herrero et al. 2012 [NGC 7771+7770]).

In the following section we collate published observed and derived properties of the Mice galaxies. Details of the observations taken as part of the CALIFA survey are given in Section 3. We study the morphology, gas and stellar kinematics of the Mice galaxies in Section 4, including a new image decomposition of the archival HST images. In Section 5 we use the stellar continuum to constrain the star formation history of the galaxies. We present maps of emission line strengths and ratios in Section 6. In Section 7 we collate multiwavelength observations from the literature to obtain an accurate estimate of the ongoing star formation in the Mice galaxies. In Sections 8 and 9 we discuss the origin of the high ionisation bicones in each of the galaxies. In Section 10 we present a mock integral field spectroscopy (IFS) datacube of the Mice merger, created from an hydrodynamical simulation, which we analyse using the same codes as the real data cube. We collate the results in Section 11, to reveal the extent to which the interaction has affected the properties of the progenitor galaxies.

Throughout the paper we assume a flat cosmology with $\Omega_M = 0.272$, $\Omega_\Lambda = 0.728$ and $H_0 = 70.4 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (WMAP-7)¹. Masses assume a Salpeter initial mass function unless otherwise stated. From the redshift of the Mice we obtain a distance of 95.5 Mpc, assuming negligible peculiar velocity contribution. The proximity of the Mice to the Coma cluster leads to some uncertainty on their distance; unfortunately no redshift-independent distance measures are available. At a distance of 95.5 Mpc, $1''$ corresponds to 0.44 kpc and the effective spatial resolution of the CALIFA observations ($3.7''$) is about 1.6 kpc.

2. Summary of previous observations of the Mice pre-merger

As one member of the original Toomre (1977) merger sequence, the Mice have been observed at most wavelengths available to astronomers. The basic kinematics of the Mice were first studied using long-slit spectroscopy covering the $H\alpha + [\text{N II}]$ lines (Burbidge & Burbidge 1961), who found the northern sides of both hulks to be receding. Stockton (1974) found $H\alpha$ emitting gas in the northern tail to be receding from the body of NGC 4676A with a velocity of 250 km s^{-1} at a distance of $90''$ (40 kpc). Barnes (2004) presented a hydrodynamic simulation of the Mice, where a reasonable match to the observed hydrogen gas dynamics was obtained. In the remainder of this Section we give a brief summary of the known physical properties of the two galaxies, based on previous observations. These properties are collated in Table 1. We focus on each galaxy in turn.

The northern NGC 4676A is a massive, gas-rich, actively star-forming disk galaxy, viewed almost edge-on. It was classified as an S0 galaxy by de Vaucouleurs et al. (1991), although we suggest a revised classification below. From neutral Hydrogen and optical observations, it is estimated to have a dynamical mass within the optical disk of $7.4 \times 10^{10} M_\odot$ (Hibbard & van Gorkom 1996). Molecular gas is primarily located in a central disk with scalelength of 2 kpc and thickness of 270 pc and this disk has a large molecular-to-dynamical mass ratio of 20% (Yun & Hibbard 2001). The two galaxies were not individually resolved by IRAS, but recent Spitzer Space Telescope observations

Notes. Physical parameters have been converted to the same distance and Hubble parameter used in this paper (95.5 Mpc; $H_0 = 70.4 \text{ km s}^{-1} \text{ Mpc}^{-1}$). The unresolved pair is also known as Arp 242 and IRAS 12437+3059. ^(a) From H I 21cm (de Vaucouleurs et al. 1991). ^(b) From a growth curve analysis of the SDSS *r*-band image (Walcher et al. in prep.). The SDSS catalogue magnitude for NGC 4676B is incorrect (see also Section 5.3). ^(c) Hibbard & van Gorkom (1996). ^(d) Yun & Hibbard (2001) for NGC 4676A and Casoli et al. (1991) for NGC 4676B. ^(e) From optical extent and H I line width (Hibbard & van Gorkom 1996). ^(f) L_{FIR} as defined by Helou et al. (1988). The Mice are not individually resolved by IRAS; these estimates from Yun & Hibbard (2001) are from the total FIR flux and 1.4GHz radio continuum ratio. ^(g) González-Martín et al. (2009).

find that NGC 4676A accounts for 83% of the total $24 \mu\text{m}$ flux of the system (Smith et al. 2007, and Section 7). Previous estimates of its star formation rate (SFR) range from $\sim 1 M_\odot \text{ yr}^{-1}$ from a narrow band H α image where corrections for [N II] emission, stellar absorption, dust attenuation or non-stellar emission were not possible (Mihos et al. 1993), to $10 M_\odot \text{ yr}^{-1}$ using the unresolved IRAS flux and resolved radio continuum (Hibbard & van Gorkom 1996; Yun & Hibbard 2001). We update this estimate in Section 7 using the full multi-wavelength information available to us today. The steep mid-IR continuum of NGC 4676A suggests a high global heating intensity compared to normal star-forming galaxies, perhaps caused by a nuclear starburst (Dale et al. 2000; Haan et al. 2011).

NGC 4676A has LINER-like optical emission line ratios (Keel et al. 1985), but has a diffuse X-ray morphology, leading González-Martín et al. (2009) to conclude that NGC 4676A does not harbour an AGN. Plumes of H α extending along the minor-axis of NGC 4676A were identified by Hibbard & van Gorkom (1996). These have been linked to outflowing gas from the nucleus, coincident with diffuse soft X-ray emission (Read 2003). The unusually high ionised-to-neutral (7.7/11.3 μm) PAH ratio found to the east of the nucleus by Haan et al. (2011) may also be associated with this outflow, or its driving source.

The south-east NGC 4676B is a massive, strongly barred spiral galaxy. Its faintness at FIR wavelengths indicates a lower overall star formation rate than its partner, and the mid-IR continuum shape suggests a star formation intensity consistent with normal star-forming galaxies (Dale et al. 2000; Haan et al. 2011). The dynamical mass within the optical disk is measured to be $1.29 \times 10^{11} M_\odot$ (Hibbard & van Gorkom 1996), about 50% larger than that of NGC 4676A. Concentrations of molecular gas are located at either end of the strong bar (Yun & Hibbard 2001). Single-dish CO observations by Casoli et al. (1991) result in a CO line flux that is a factor of 2.5 greater than the interferometric measurement of Yun & Hibbard (2001), which suggests that a large fraction of the molecular gas in NGC 4676B is either low surface brightness or extended over scales larger than those probed by the interferometric observations ($\theta > 45''$, 20 kpc). The total Hydrogen mass of NGC 4676B is a little lower than that of NGC 4676A (Hibbard & van Gorkom 1996); given its

larger dynamical mass, NGC 4676B has a significantly lower gas mass fraction than NGC 4676A.

With a LINER-like emission line spectrum (Keel et al. 1985), compact X-ray emission and a detection in hard X-rays ($L_{2-10} = 1.48 \times 10^{40} \text{ erg s}^{-1}$), NGC 4676B is classified as a “candidate” AGN by González-Martín et al. (2009). Additional evidence for the presence of an AGN comes from: (i) the unusually high ratio of excited H $_2$ emission to PAH emission (Haan et al. 2011), consistent with additional excitation of H $_2$ by hard X-rays from a central AGN (Roussel et al. 2007); (ii) the hard X-ray emission is offset from the nuclear H α emission (Masegosa et al. 2011), showing that the hard X-rays are not related to a nuclear starburst.

In summary, previous observations have shown that NGC 4676A is an edge-on disk, rich in dust, molecular and atomic gas, while NGC 4676B is a strongly barred, inclined disk, with a lower gas mass fraction. There is some evidence for a low luminosity AGN in NGC 4676B, but no evidence for an AGN in NGC 4676A. A bipolar outflow is found in NGC 4676A. Table 1 summarises the properties of the Mice galaxies that can be found in the literature.

3. The CALIFA Data

The Calar Alto Legacy Integral Field Area (CALIFA) survey, currently in progress on the 3.5m Calar Alto telescope in Spain, aims to obtain spatially resolved spectra of 600 local galaxies spanning the full colour-magnitude diagram, with the PPAK integral field unit (IFU) of the PMAS instrument (Roth et al. 2005). The galaxies are diameter selected to be volume correctable from the seventh data release (DR7) of the Sloan Digital Sky Survey (SDSS). Observations are performed using two overlapping grating setups (V500 and V1200), with resolutions of 6.3Å and 2.3Å (FWHM) and wavelength ranges of 3745–7500Å and 3650–4840Å respectively (velocity resolution, $\sigma \sim 100$ –210 km s^{-1} and 60–80 km s^{-1}). The spectrophotometric calibration accuracy is close to that achieved by the SDSS DR7. The large field-of-view of PPAK (1.3 \square') allows coverage of the full optical extent of the galaxies. The datacubes reach a 3σ limiting surface brightness of 23.0 mag/arcsec² for the V500 grating

Fig. 2. The $H\alpha$ map of the Mice galaxies with examples of V500 CALIFA spectra, extracted from key regions. For the nucleus and knots of both galaxies the spectra are extracted using a circular aperture of $2''$ radius, for the tail and outflow regions in NGC 4676A an elliptical aperture of $4'' \times 3''$ was extracted.

data and $22.8 \text{ mag/arcsec}^2$ for V1200. The survey is described in detail in the presentation article (Sánchez et al. 2012a) and first Data Release article (DR1, Husemann et al. 2013).

Observations of the Mice galaxies were taken during the nights of 2011-05-04 (V500), 2011-05-05 (V1200) and 2011-06-29 (V1200). Three dithered pointings were made, centred around each of the two galaxy nuclei, with exposure times of 900 s per pointing for V500 and 2×900 s for V1200. The PPAK IFU data of the Mice were reduced with the dedicated CALIFA data reduction pipeline and are available to the public as part of DR1. The basic outline of the pipeline is given in Sánchez et al. (2012a), with significant improvements made for the DR1 release and described in Husemann et al. (2013). In addition to the data available in the public release, a combined cube with observations from both gratings was created to improve the vignetting of the blue and red end of the V500 and V1200 data respectively. Wavelengths shorter (longer) than 4500\AA originate from the V1200 (V500) data, with the V1200 data cube degraded to the spectral resolution of the V500 data. The V500 and degraded V1200 cubes were then spatially co-registered during the process of differential atmospheric refraction (DAR) correction and their relative spectrophotometry matched in the overlapping spectral regions before being combined into a single cube.

Finally, for the purposes of presentation in this paper, the cubes for NGC 4676A and NGC 4676B were cropped diagonally between the galaxies and joined to form a single cube, with the relative offset between the two nuclei determined from their SDSS centroids. This procedure is only astrometrically accurate to within the size of the spaxels, i.e. $1''$, which was deemed sufficient given the spatial resolution of the data of $\sim 3.7''$. Voronoi binning was performed on the individual cubes, in order to retain independence of the two sets of observations.

Figure 2 presents the $H\alpha$ emission line intensity map of the Mice galaxies, measured from the V500 data, and provides examples of spectra extracted from key regions of interest.

4. Morphology and kinematics

We begin by combining archival HST imaging and CALIFA spectroscopy to build a global picture of the morphology and kinematics of the merging galaxies.

4.1. Image decomposition

To measure the main morphological components of the Mice galaxies we use GALFIT 3.0 (Peng et al. 2010) on the archival HST ACS F814W image. The instrumental point-spread-function (PSF) was synthesised using TinyTim; Galactic stars, tidal arms and prominent dust lanes in NGC 4676A were masked using SExtractor. The parameters of the fit are presented in Table 2.

We find that NGC 4676A is dominated by an edge-on disk and/or bar. No evidence could be found for either a nuclear point source or bulge, although the central dust lanes may still hide these components. The boxy shape apparent in the HST image could arise from vertical motions of stars in a bar, rather than a bulge (e.g. Bureau & Athanassoula 1999, 2005; Kuijken & Merrifield 1995; Lang et al. 2014; Martínez-Valpuesta et al. 2006; Williams et al. 2011), and the model fit improves upon inclusion of a Ferrer bar component. Our results show that the previous classification of NGC 4676A as an S0 galaxy is likely incorrect (de Vaucouleurs et al. 1991), and SBd is more appropriate. This revised classification is also consistent with the high dust and gas content of the galaxy.

The inclination of NGC 4676B allows the identification of a strong bar, although our simple image decomposition is unable to separate the bar from the disk component. By ellipse fitting the HST image isophotes using the method presented in Aguerri et al. (2009), we find the radius of the bar in NGC 4676B to be $10''$ (4.4 kpc) and position angle (PA) $\sim 20^\circ$. This is consistent with the peaks of CO, separated by $\sim 16''$ and thought to lie at either end of the bar. A significant bulge is required to obtain a good fit. Including a nuclear point-source component also improves the fit slightly and decreases the Sérsic index of the bulge as expected (Gadotti 2008). The best fit model has a bulge-to-total flux ratio of ~ 0.5 i.e. an S0/a galaxy (Simien & de Vaucouleurs 1986).

4.2. Stellar kinematics

The stellar kinematics of the Mice galaxies are measured from the V1200 grating datacube using the penalised pixel-fitting (pPXF) method of Cappellari & Emsellem (2004). Full details of the method will be given in Falcón-Barroso et al. (in prep.).

Table 2. Results of a GALFIT 3.0 decomposition of the HST ACS F814W image.

Component	magnitude	parameters
A : Edge-on Disk	14.7: ^a	edgedisk: $\mu_0=21.8$; $h_s=3.5$; $r_s=29$; PA= 5
A : Bar	14.1 ^a	ferr2: $\mu_{FWHM}=19.7$; $R_{trunc}=19$; $\alpha=2$; $\beta=1$; $b/a=0.6$; PA= 4
B : Bulge	14.2	Sérsic: $R_e=6.0$; $n=4.3$; $b/a=0.75$; PA=-26
B : Disk+Bar	13.8	expdisk: $R_s=6.2$; $b/a=0.4$; PA= 36
B : Point source	20.9:	PSF

Notes. Parameters are given as described in the GALFIT documentation. Length scales are in arcseconds, position angles are from N to E (anti-clockwise in the figures) and surface brightnesses are in mag/arcsec². Parameter values should be taken as indicative only, and those marked with “:” are particularly uncertain due to the complex morphology of the system. ^(a) Measured from the model image.

Briefly, a non-negative linear combination of a subset of 328 stellar templates from the Indo-US library (Valdes et al. 2004) covering a full range of stellar parameters (T_{eff} , $\log(g)$, $[Fe/H]$) is fit to the spectra, following a Voronoi binning of spaxels to achieve a minimum signal-to-noise (SNR) of 20 (Cappellari & Copin 2003). These Voronoi binned spaxels are termed “voxels”, and the effective spatial resolution of Voronoi binned maps is naturally degraded below the CALIFA effective resolution of 3.7” in the outer regions. In the computation of the SNR we have taken into account the correlation among the different spectra in the datacube as explained in Husemann et al. (2013). Spaxels in the original V1200 datacube with per pixel SNR < 3 are deemed unreliable and not included in the analysis. Emission lines in the covered wavelength range are masked during the fitting procedure (i.e. [O II], [Ne III], H δ , H γ , [O III], He II, and [Ar IV]). Error estimates are determined via Monte Carlo simulations, and are typically 5 (10) km s⁻¹ for velocities and dispersions in the inner (outer) voxels. Velocity dispersions are corrected for instrumental resolution during the fitting process, velocity dispersions below ~35 km s⁻¹ are unresolved at the resolution of the data.

The stellar velocity and velocity dispersion maps are shown in the top panels of Figure 3, where the systemic redshift of the system is taken as the velocity of the stars in the central 5” of NGC 4676A. The nucleus of NGC 4676A is receding at ~160 km s⁻¹ relative to the nucleus of NGC 4676B. The stellar kinematics of the main body of NGC 4676A show a rotating edge-on disk, with rotation axis coincident with the minor disk axis. This rotation continues into the northern tidal tail, which is receding at 130 km s⁻¹ relative to the nucleus of NGC 4676A in the northernmost voxel (30-35” from the nucleus). No evidence for a classical bulge is seen in this galaxy, with low nuclear velocity dispersion and constant rotation with height above the major axis. This supports the results from the image analysis above. However, given the disturbed nature of the system and the high dust attenuation close to the nucleus, high spatial resolution longer wavelength observations would be required to give a robust upper limit on bulge size. We note that we are unable to identify “pseudo” bulges at the spatial resolution of the CALIFA data.

The stellar velocity field of NGC 4676B shows a twisted inclined disk (Z or S-shaped isovelocity contours), with the inner rotation axis offset from the minor axis of the disk. A direct analysis of the kinematic maps provides a quantitative measurement of the kinematic centres and PAs of the galaxies (see Barrera-Ballesteros et al. 2014, for details of the method). For a radius internal to 10” we measure receding and approaching stellar kinematic PAs of 165 and 150 degrees respectively (anti-clockwise from north), compared to a morphological PA of 33 degrees, confirming that the dominant rotation in the inner regions is around the major axis of the galaxy. The classical bulge in NGC 4676B is clearly visible from the significant increase in

velocity dispersion in the centre of the galaxy, confirming the results from the morphological decomposition.

4.3. Ionised gas kinematics

We measure the ionised gas kinematics from the H α line in the V500 datacube, favouring the increased SNR provided by the stronger H α line, over the higher velocity resolution afforded by the weaker lines in the V1200 cube. We verified that our results are consistent with those derived from [O II] in the higher spectral resolution V1200 datacube in the inner high surface brightness regions. We use standard IRAF routines to fit simultaneously three Gaussian line profiles to H α and the two [N II] lines, with both amplitude and width free to vary independently, in every spaxel that is included in the H α emission line quality mask described in Section 6. The instrumental resolution was subtracted from the measured line widths in quadrature ($\sigma = 116$ km s⁻¹ at the wavelength of H α). Typical errors on the line velocities were estimated to be ~15 km s⁻¹ from fitting different species. Line widths below ~58 km s⁻¹ are unresolved at the CALIFA resolution.

The ionised gas kinematics derived from the H α emission line are shown in the bottom panels of Figure 3. The same global kinematics are seen as in the stellar kinematics: NGC 4676A is dominated by a rotating edge-on disk and NGC 4676B by a twisted disk inclined to the line-of-sight. Evidence of a dynamically hot bulge is seen in NGC 4676B, but not in NGC 4676A. The receding and approaching kinematic PAs of the ionised gas disk in NGC 4676B are 350 and 161 degrees respectively, consistent with those of the stars i.e. the twist in the disk is as strong in both the stellar and ionised gas kinematic fields. The ionised gas in the N-E spiral arm of NGC 4676B and northern tidal tail of NGC 4676A are the dynamically coldest regions of the system with observed line widths close to the resolution of the CALIFA data, implying velocity dispersions below ~58 km s⁻¹. The ionised gas in the tail of NGC 4676A is receding at ~180 km s⁻¹, relative to the body of NGC 4676A, at a distance of ~35”. This is in agreement with long-slit observations by Stockton (1974).

The zero-velocity curve of the ionised gas in NGC 4676A shows a V-shape along the minor axis, indicating lower line-of-sight velocities above the plane of the disk than within the disk. This extra-planar gas also shows enhanced velocity dispersion, in streamers extending radially outwards from the nucleus in the same direction as the soft X-ray emission (Read 2003). These are dynamical signatures of outflowing gas, i.e. a galactic superwind, which we will return to discuss in more detail in Section 8. Additional regions of high velocity dispersion are observed close to the nucleus of NGC 4676B. In this case, the velocity gradient is high and this effect might be equivalent to “beam smearing”

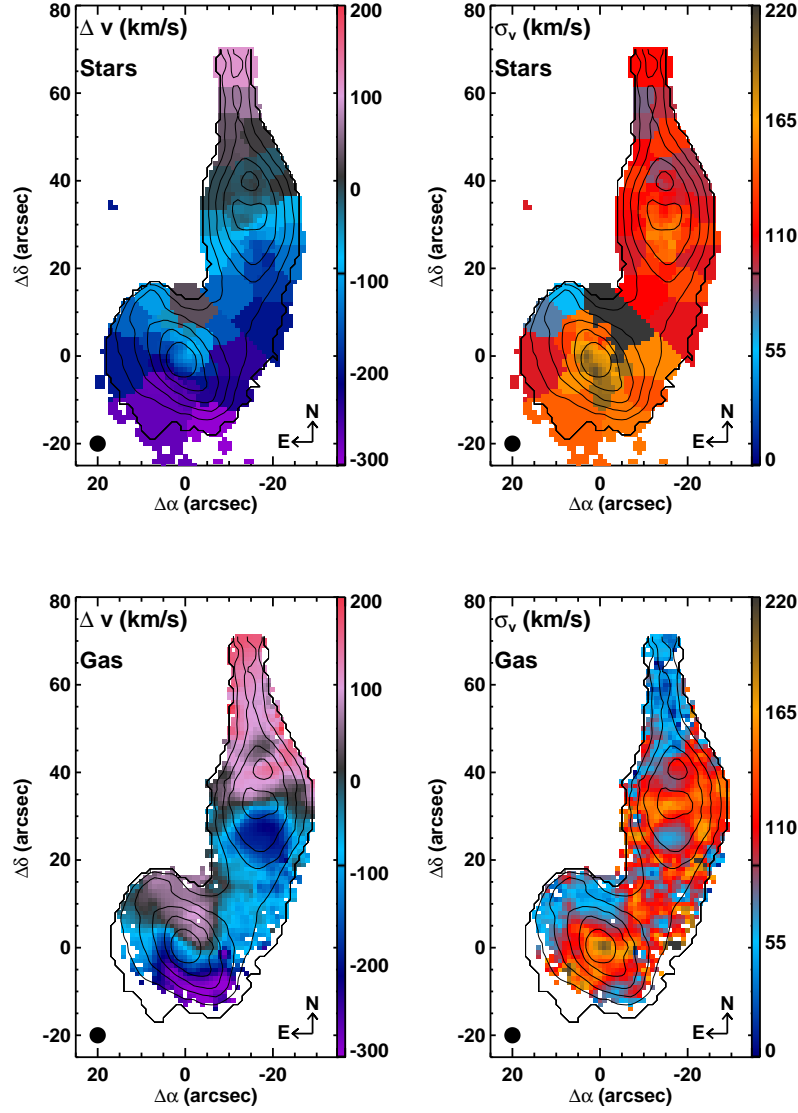

Fig. 3. Stellar (top) and ionised gas (bottom) velocity field (left) and velocity dispersion (right). The ionised gas maps are measured from the $H\alpha$ emission line in the V500 grating. Velocities are relative to 6652 km s^{-1} which corresponds to the heliocentric velocity of stars measured within the central $5''$ of NGC 4676A. The velocity dispersion maps have been corrected for instrumental resolution; velocity dispersions below $\sim 35 \text{ km s}^{-1}$ for stars and $\sim 58 \text{ km s}^{-1}$ for the gas are unresolved at the instrumental resolution. Typical errors are $5\text{--}10 \text{ km s}^{-1}$ for the stellar velocities and 15 km s^{-1} for the ionised gas. In these maps and all the following maps, the black contours indicate V -band isophotes with the outermost contour at 23 mag/arcsec^2 and contours spaced by 0.6 mag/arcsec^2 . The black circle shows the effective spatial resolution of the CALIFA observations before Voronoi binning of the data.

seen in $H I$ surveys, where multiple components are observed in a single resolution element ($3.7''$ in the case of CALIFA).

We detect a blueshift of 30 km s^{-1} of the gas relative to stars in the nucleus of NGC 4676A, and an 88 km s^{-1} redshift of the gas relative to the stars in the nucleus of NGC 4676B. In the case of NGC 4676A this is a clear case for an outflow with some transverse velocity component. The cause of the offset for NGC 4676B is less obvious, but may be due to a tidal component passing in front of the bulge and contributing significantly to the $H\alpha$ luminosity.

The spectral resolution of CALIFA is not sufficient to identify dynamically distinct components in the emission lines, however measurements of line asymmetries indicate where such multiple components may exist. Following the cross-correlation method of García-Lorenzo (2013) for the $[O III]$ emission line we

find a mixture of blue- and redshifted asymmetries in the western bicone of NGC 4676A, again consistent with gas outflowing in bicones perpendicular to the disk.

5. Stellar populations

In this section we use the stellar continuum shape and strength of stellar absorption features to characterise the spatially resolved properties of the stellar population and constrain the stellar masses and star formation history of each galaxy. From the simulations of Barnes (2004) we expect first passage to have occurred about 170 Myr ago, and optical spectra of star clusters indicate some star formation occurred at that time (Chien et al. 2007). Here we investigate how wide spread that star formation was and whether it has continued to the time of observation.

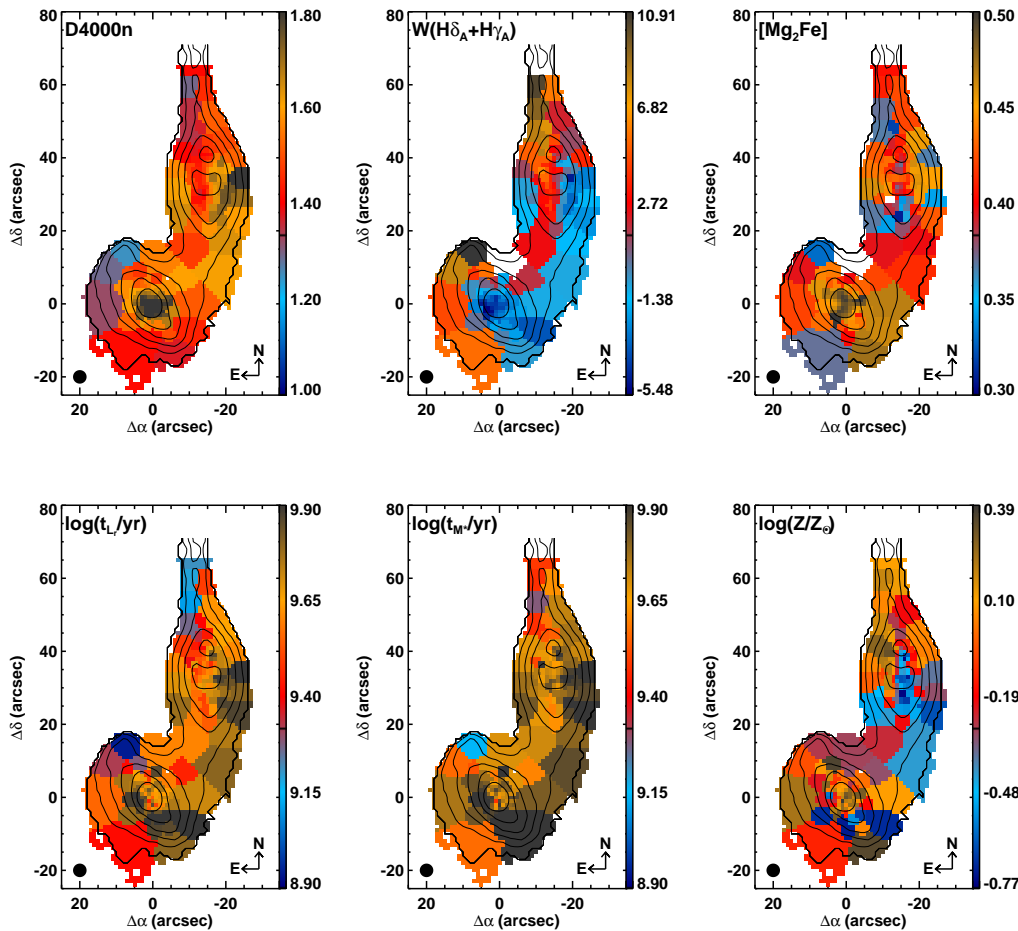

Fig. 4. *Top:* Maps of three commonly used spectral line indices: the 4000Å break strength (D_{4000n}); the combined equivalent width of the higher-order Balmer absorption lines $H\delta_A$ and $H\gamma_A$ (in Å); the Lick index $[Mg_2Fe]$. *Bottom:* Mean light-weighted age in the r -band, stellar mass-weighted age, and stellar metallicity. These have been measured from comparison of the line indices to stellar population synthesis models.

The stellar population analysis is performed on the combined V500 and V1200 cube, using the same Voronoi binning as for the stellar kinematics. While it is difficult to quantify the uncertainties associated with the extraction of physical properties from stellar population model fitting (see e.g. Conroy et al. 2009; Panter et al. 2007), Cid Fernandes et al. (2014) present an analysis of the errors caused by use of different spectral synthesis models and spectrophotometric calibration, applied to the CALIFA data. They find that noise and shape-related errors at the level expected for CALIFA lead to uncertainties of 0.10–0.15 dex in stellar masses, light-weighted mean ages and metallicities, with larger uncertainties on star formation histories and therefore on mass-weighted quantities. There are even larger uncertainties associated with the choice of population synthesis model, at the level of 0.2–0.3 dex. For this reason, we present raw line index maps alongside derived quantities.

5.1. Spectral indices

We measure five standard stellar absorption line indices from emission line subtracted spectra: the 4000Å-break (D_{4000n}), the Balmer absorption lines $H\beta$ and $H\delta_A + H\gamma_A$, and two composite metallicity-sensitive indices $[Mg_2Fe]$ and $[MgFe]$ as defined in Bruzual & Charlot (2003) and Thomas et al. (2003), respectively. Emission lines detected at greater than 3σ significance are sub-

tracted from the stellar continuum using a Gaussian broadened template. Physical properties are then derived through comparison of the line indices to a “stochastic burst” library of stellar population synthesis models (Bruzual & Charlot 2003), following the same Bayesian approach as described in Gallazzi et al. (2005). Typical errors on mean ages are ~ 0.12 dex, varying between 0.1 and 0.2 dex.

Maps of three of the measured spectral indices are shown in the upper panels of Figure 4. Derived properties of light-weighted and mass-weighted mean stellar age and metallicity are shown in the bottom panels. The strength of the 4000Å break (top left) correlates to first-order with mean stellar age, averaged over timescales of several Gyr, and to second-order with metallicity, particularly in the older stellar populations. The strength of the higher order Balmer absorption lines (top centre) measures mean stellar age over a slightly shorter period of ~ 0.5 Gyr. Both the central region of NGC 4676B (in the bulge), together with the east and west flanks of NGC 4676A (above and below the disk), show strong break strengths indicating older mean stellar ages than in the disks of the two galaxies. The region with the youngest mean stellar age is the north-east (NE) tidal arm of NGC 4676B. In star-forming galaxies the strength of the Balmer lines and 4000Å break strength are strongly inversely correlated. It is therefore not surprising that (the inverse of) the Balmer line index map is not dissimilar to that of D_{4000} , although with a

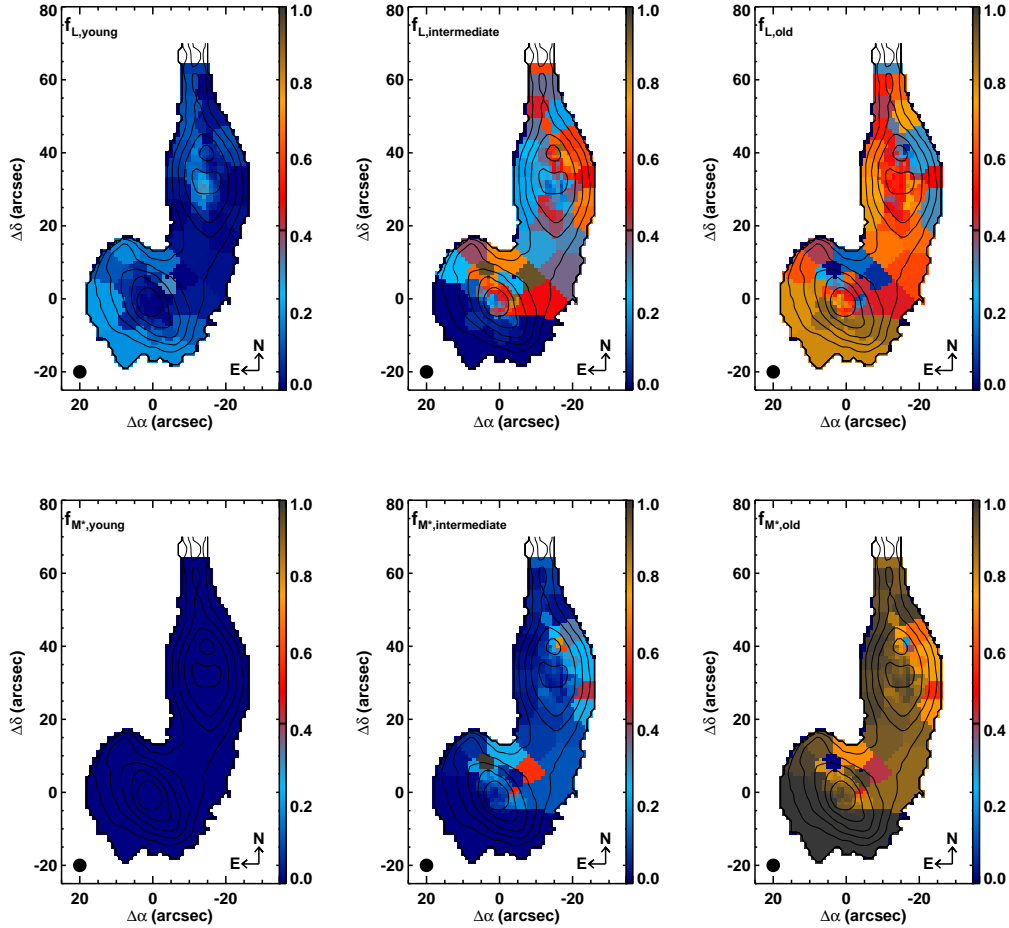

Fig. 5. The fraction of light at 5635Å (top panels) and mass (lower panels) contributed by young ($t < 140$ Myr), intermediate ($140 \text{ Myr} < t < 1.4$ Gyr) and old ($t > 1.4$ Gyr) populations.

slightly lower SNR². The right hand panel shows the metallicity sensitive index, [Mg₂Fe]. Both the bulge of NGC 4676B and regions above and below the disk plane of NGC 4676A show stronger [Mg₂Fe] than the disks, indicating a more metal rich stellar population. The index [MgFe]’ shows similar results.

Converting these observables into physical properties in the lower panels of Figure 4, we find that the stars of both galaxies are predominantly older than several Gyrs. Only the northern tidal tail and the NE arm of NGC 4676B have distinctly younger stellar populations, with light-weighted ages of ~ 0.6 Gyr or mass-weighted ages of ~ 2.5 Gyr. The bulge of NGC 4676B and regions above and below the disk of NGC 4676A have the oldest mean stellar ages of $\gtrsim 4.5$ Gyr. There is no evidence for a significant intermediate age population that would be consistent with having formed during first passage, therefore it is clear that the merger has not yet had a significant impact on the stellar populations.

² Note that the negative equivalent widths of the Balmer lines do not indicate emission, measured values as low as -10 are expected for old stellar populations (see Gallazzi et al. 2005, for the expected values for SDSS galaxies).

5.2. Young, intermediate age and old populations

To visualise the spatially resolved star formation history of the galaxies, we turn to the full-spectrum fitting package *STARLIGHT* (Cid Fernandes et al. 2005, 2013). This inverts the observed spectrum into stellar populations of different ages, rather than fitting a library of models with analytic star formation histories, as was done in the previous section. *STARLIGHT* fits the full wavelength range with combinations of simple stellar population (SSP) spectra from the population synthesis models of Vazdekis et al. (2010) and González Delgado et al. (2005), using the Granada (Martins et al. 2005) and MILES (Sánchez-Blázquez et al. 2006) stellar libraries, dust extinction following the Cardelli et al. (1989) law, a Salpeter IMF, and stellar evolutionary tracks from Girardi et al. (2000). The SSP ages range from 1 Myr to 14 Gyr and SSPs of four different metallicities are included ($Z = 0.0004, 0.008, 0.020, 0.033$, where $Z_{\odot} \sim 0.02$ for these models). Emission lines are masked during the fit, and errors propagated from the CALIFA error arrays.

Figure 5 shows maps of the fraction of light at 5635Å and mass arising from stars of different ages. We select age bins that correspond to the main sequence lifetimes of stars with distinctly different optical line and continuum features, namely young ($t < 140$ Myr), intermediate ($140 \text{ Myr} < t < 1.4$ Gyr) and old ($t > 1.4$ Gyr) populations, in order to maximise the robustness of the spectral decomposition results.

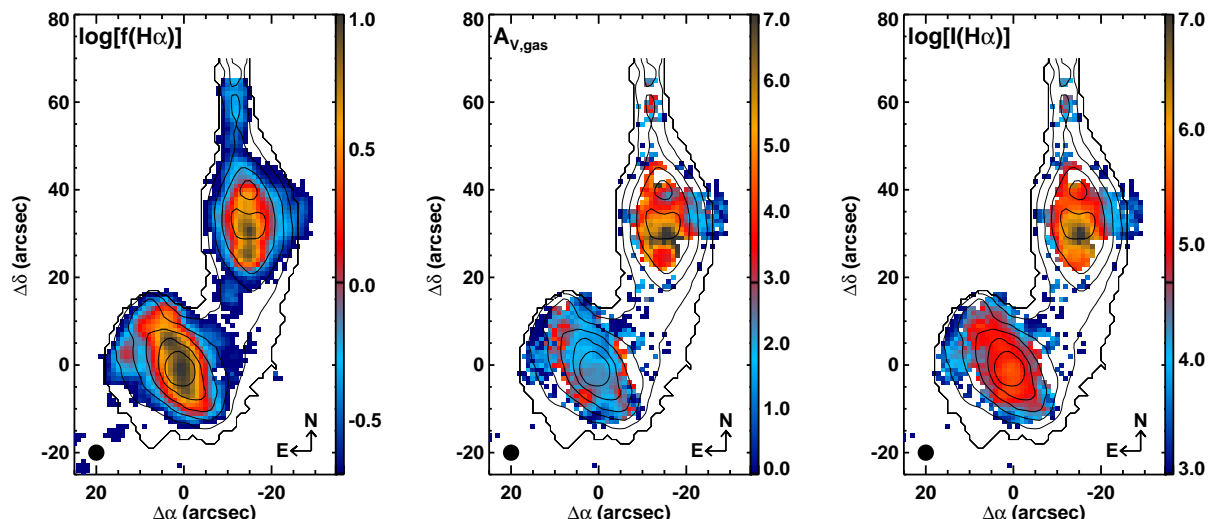

Fig. 6. *Left:* $H\alpha$ emission line flux ($10^{-16}\text{erg s}^{-1}\text{cm}^{-2}\text{arcsec}^{-2}$). *Centre:* Emission line attenuation at 5500\AA (magnitudes), calculated from the observed $H\alpha/H\beta$ emission line ratio and dust attenuation law suitable for emission lines in low redshift star-forming galaxies (Wild et al. 2011). *Right:* dust attenuation corrected $H\alpha$ luminosity surface density ($L_{\odot}\text{kpc}^{-2}$).

Clearly the ongoing merger has thus far had little significant affect on the stellar populations in terms of total stellar mass or global star formation history. The fraction of stellar mass contributed by stars younger than 140 Myr is less than 5% in all regions, although $\sim 30\%$ of optical light in the nuclear regions of NGC 4676A and tidal arm of NGC 4676B arises from stars younger than 140 Myr. In most regions $> 90\%$ of the stellar mass is from stars older than 1.4 Gyr. There is an excess of light from intermediate age stars seen in the western half of NGC 4676A, inter-galaxy region, and NE bar of NGC 4676B, compared to the disks of these galaxies. This is consistent with the triggering of low level star formation in the gas flung out from the galaxy disks at first passage ~ 170 Myr ago, perhaps through dynamic instabilities or shocks (see e.g. Boquien et al. 2010, and references therein).

5.3. Stellar mass and star formation rate

From the integrated star formation history measured by STARLIGHT, and correcting for recycling of matter back into the interstellar medium (ISM), we obtain a total current stellar mass of 1.2×10^{11} and $1.5 \times 10^{11} M_{\odot}$ for NGC 4676A and B respectively, for a Salpeter IMF. For NGC 4676A the CALIFA derived stellar mass agrees well with that derived from SDSS 5-band photometry ($1.6 \times 10^{11} M_{\odot}$, J. Brinchmann³). For NGC 4676B the SDSS derived mass is 10 times lower, which is traceable to incorrect photometric measurements in all bands in the SDSS catalogue, presumably caused by the deblending algorithm which has identified three sources in this galaxy. The higher stellar masses than dynamical masses (Table 1) may be due to the assumed Salpeter IMF or difficulty in measuring a dynamical mass from a kinematically disturbed system. The use of a Chabrier IMF would solve the discrepancy.

³ The SDSS catalogue can be downloaded from here: http://home.strw.leidenuniv.nl/~jarle/SDSS/DR7/totlgm_dr7_v5_2.fit.gz SDSS mass was increased by a factor of 1.8 to convert from a Chabrier to Salpeter IMF.

The decomposition of the stellar continuum can provide an approximate estimate of the ongoing star formation rate in the galaxies, independent of the ionised gas emission. The value obtained depends sensitively on the width of the time bin over which the average is calculated. Varying the width of the time bin between 25 and 140 Myr yields a global SFR of $2.6\text{--}5 M_{\odot}\text{yr}^{-1}$ and $1\text{--}4 M_{\odot}\text{yr}^{-1}$ for NGC 4676A and B respectively. While the errors on these values are difficult to quantify, it is clear that neither galaxy is currently undergoing a significant burst of star-formation, especially when their very large stellar masses are taken into account.

The young stellar population found in the centre of NGC 4676A implies a nuclear SFR surface density of $\sim 0.15 M_{\odot}\text{yr}^{-1}\text{kpc}^{-2}$, averaged over 140 Myr in the inner $5 \times 5''$. No young stellar population is found in the central regions of NGC 4676B.

6. Ionised gas emission

One of the highlights of the CALIFA dataset is its wide wavelength coverage, allowing measurements of all the strong emission line species from $[\text{O II}]\lambda 3727$ to $[\text{S II}]\lambda 6731$. We measure the total emission line fluxes in each spaxel by fitting Gaussian line profiles to the stellar continuum subtracted spectra using the IFU package fit3D (see e.g. Sánchez et al. 2007).

We use empirically derived flux thresholds to remove spaxels from the analysis where the surface brightness is too low to obtain a reliable line flux. For $H\alpha$ and line ratios which include $H\alpha$ we use a flux threshold of $1.5 \times 10^{-17}\text{erg s}^{-1}\text{cm}^{-2}$, and for $H\beta$ and line ratios which include $H\beta$ we use a flux threshold of $5 \times 10^{-18}\text{erg s}^{-1}\text{cm}^{-2}$. Low SNR spectra at the outskirts of the maps are visually checked to ensure that their line measurements are reasonable. In order to measure emission line strengths in the fainter outer regions, we performed the same analysis on a Voronoi-binned data cube. However, we found that no significant additional information was gained from these maps, and some information was lost due to the lack of connection between Voronoi bin boundaries and physical components.

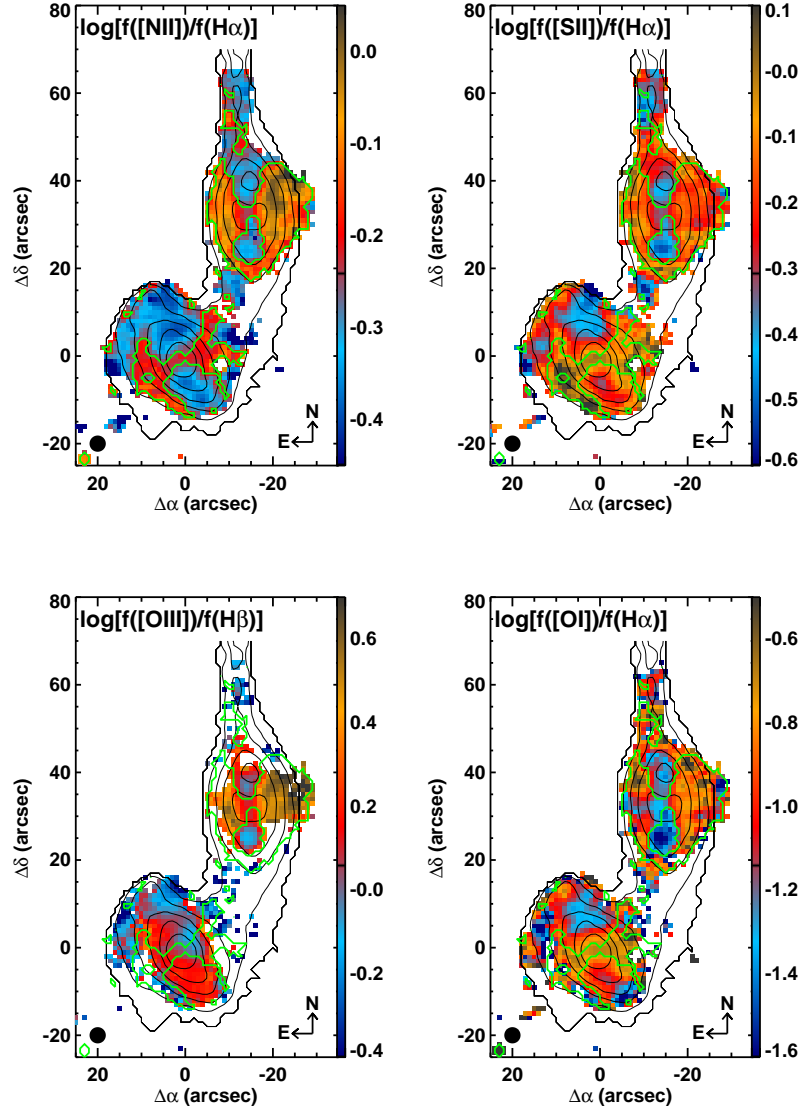

Fig. 7. From top left to bottom right: emission line flux ratio maps for $[\text{N II}]\lambda 6583/\text{H}\alpha$, $([\text{S II}]\lambda 6717 + [\text{S II}]\lambda 6731)/\text{H}\alpha$, $[\text{O III}]\lambda 5007/\text{H}\beta$ and $[\text{O I}]\lambda 6300/\text{H}\alpha$. To guide the eye in comparison between panels the black contours indicate V -band isophotes, and the thick green contours delineate those regions with $\log([\text{N II}]/\text{H}\alpha) > -0.25$.

6.1. $\text{H}\alpha$ emission and dust attenuation

The CALIFA datacubes have sufficient continuum SNR, spectral resolution and wavelength range to allow subtraction of the stellar absorption from the Balmer emission lines. This allows us to measure the dust attenuation affecting the nebular lines and thus estimate the intrinsic distribution of ionised gas. The dust attenuation ($A_{\text{V,gas}}$) map is constructed from the $\text{H}\alpha/\text{H}\beta$ ratio map using the attenuation law from Wild et al. (2011) which is measured from, and applicable to, emission lines in local star-forming galaxies including local ULIRGs.

Figure 6 shows the observed $\text{H}\alpha$ line flux, the emission line attenuation map ($A_{\text{V,gas}}$) and the dust-attenuation corrected (intrinsic) $\text{H}\alpha$ line luminosity. The three peaks in observed $\text{H}\alpha$ flux along the disk of NGC 4676A have been noted previously in the literature. The ionised gas bar of NGC 4676B is clear, with the axis of the bar offset by about 25° in the clockwise direction from the major axis of the continuum light profile (contours).

We measure a maximum effective attenuation of ~ 7 magnitudes at 5500\AA close to the centre of NGC 4676A, which is consistent with the dust lane visible in the HST images. For such large attenuations, small variations in the assumed dust attenuation law or stellar population models result in significant uncertainties in the dust-corrected line fluxes. We show below that the dust attenuation corrected total $\text{H}\alpha$ flux is a factor of a few larger than expected from multiwavelength observations (Section 7 and Table 3). After correcting for dust attenuation we find that ionised hydrogen emission in NGC 4676A is concentrated in the central regions of the galaxy.

NGC 4676B has an average line extinction of a little over ~ 1 magnitude, typical for an ordinary star-forming galaxy. The dust content of the disk appears slightly higher than the bar. We note that $\text{H}\alpha$ emission is seen even in the region dominated by the old stellar bulge. Either there are sufficient young stars are available to ionise the gas, even though the continuum light is completely dominated by old stars (Section 5), or the gas in the

Fig. 8. Map of the [S II] doublet ratio ($[S II]_{\lambda 6717}/[S II]_{\lambda 6731}$), a sensitive electron density estimator. Higher density gas has lower ratios. The thin black contours show V-band continuum flux, and the thick green contours delineate those regions with $\log([N II]/H\alpha) > -0.25$.

central regions is primarily ionised by the AGN. Alternatively, the ionised gas is not coincident with the bulge, which would also be consistent with the offset in velocities (Section 4)

6.2. Emission line ratios sensitive to ionisation source

Standard line ratios sensitive to the shape of the ionising spectrum have been calculated and the spatial distribution of a selection of these are shown in Figure 7. We focus on pairs of lines that are close enough in wavelength space for their ratios to not be strongly affected by dust attenuation. The most obvious feature of these maps are the butterfly shaped bicones of higher ionisation gas orientated along the minor axes of both galaxies. Comparing the four line ratio maps, the bicones in the two galaxies are clearly different: in NGC 4676A the bicones are visible in all maps, in NGC 4676B the bicones have higher $[S II]/H\alpha$, $[N II]/H\alpha$, and $[O I]/H\alpha$ line ratios, but are not visible in $[O III]/H\beta$. High ionisation gas is also found following an arc to the south of NGC 4676A.

The line ratios make it clear that a substantial fraction of the line emission originates from sources other than photo-ionisation by stars. To guide the eye, we overplot contours to delineate those regions with $\log([N II]_{\lambda 6584}/H\alpha) > -0.25$, which is approximately the maximum ratio observed in high-metallicity star forming regions (Kauffmann et al. 2003). We will analyse the possible causes of these bicones in Sections 8 and 9 below.

6.3. Emission line ratios sensitive to gas density

In Figure 8 we show the $[S II]_{\lambda 6717}/[S II]_{\lambda 6731}$ doublet ratio which is primarily sensitive to the electron density of the emitting gas (n_e). This ratio varies between 0.4 and 1.4 for $n_e \gtrsim 10^5 \text{ cm}^{-3}$ and $n_e \lesssim 100 \text{ cm}^{-3}$ (at $T_e = 10^4 \text{ K}$, Osterbrock & Ferland 2006). Both galaxies show complex structure in their

gas density. Regions with particularly low density (high doublet ratio) are the NE tidal arm of NGC 4676B, and the edges of the western bicone in NGC 4676A. The apparently very high density in the outskirts of NGC 4676B and the region to the south of NGC 4676A might be due to shocks caused by the interaction and gas inflows, but higher quality data should be obtained to confirm these measurements.

The median doublet ratio in the high ionisation bicones of NGC 4676A is 1.1, which implies a typical electron density of $n_e \sim 400 \text{ cm}^{-3}$. In the very outer regions of the western cone, the median [S II] ratio increases slightly to 1.2, equivalent to an electron density of $n_e \sim 200 \text{ cm}^{-3}$. The central electron density is no higher than in the gas throughout the cones.

6.4. Gas-phase metallicities and star formation rates

We calculated metallicities from the $[O III]$ and $[N II]$ emission lines (Pettini & Pagel 2004) in regions where the line ratios indicate the gas is primarily photoionised by hot stars, i.e. in the disks of the galaxies and in the northern tidal tail. The metallicity of the gas throughout both galaxies is approximately solar, consistent with star clusters located in the tidal tails of the two galaxies (Chien et al. 2007).

We additionally note that the $[N II]/H\alpha$ ratio map is noticeably flat in the disk and bar of NGC 4676B. Given that this galaxy is massive, with a prominent central bulge, a metallicity gradient is expected (Pilyugin et al. 2004; Sánchez et al. 2012b). Flat gradients can be caused by mergers, but such a flat gradient is expected to only occur in the later stages of a merger (Kewley et al. 2010; Rupke et al. 2010a,b). The presence of a strong bar complicates the picture, and simulations by Martel et al. (2013) show that mixing of gas from the outer regions to the centre through a bar may occur even before star formation is induced.

For the regions of the galaxies where the gas is photoionised by light from stars, we can measure the SFR from the dust attenuation corrected $H\alpha$ line luminosity, using the standard conversion to star formation rate (Kennicutt 1998b). For the remaining regions we obtain only an upper limit on the SFR, because a fraction of the $H\alpha$ flux must arise from processes unrelated to star formation. For NGC 4676A we measure a total $H\alpha$ luminosity of $4.4 \times 10^{42} \text{ erg s}^{-1}$, of which $2.2 \times 10^{42} \text{ erg s}^{-1}$ (50%) arises from regions with line ratios consistent with stellar photoionisation. These lower and upper limits lead to a SFR for NGC 4676A of $17\text{--}35 \text{ M}_{\odot} \text{ yr}^{-1}$. In the same manner, for NGC 4676B we measure a total dust-attenuation corrected $H\alpha$ luminosity of $6.1 \times 10^{41} \text{ erg s}^{-1}$ of which 56% arises from regions with line ratios consistent with photoionisation by young stars. This gives a SFR for NGC 4676B of $3\text{--}5 \text{ M}_{\odot} \text{ yr}^{-1}$.

We can use the dust attenuation corrected $H\alpha$ luminosity to estimate the central SFR surface density in the inner $5 \times 5''$ of each galaxy. For NGC 4676A we find $\Sigma_{\text{SFR}} < 4 \text{ M}_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$, and for NGC 4676B we find $\Sigma_{\text{SFR}} < 0.2 \text{ M}_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$. The upper limit estimated from the dust corrected $H\alpha$ luminosity is similar to that measured from the spectral decomposition for NGC 4676B ($\sim 0 \text{ M}_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$), but much higher for NGC 4676A ($\sim 0.15 \text{ M}_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$). As previously, we note that the global dust attenuation corrected $H\alpha$ luminosity appears to overestimate the global SFR compared to other multiwavelength methods (Section 7 and Table 3). In the nuclear regions, where the dust attenuation is large, it is possible that the dust attenuation correction is leading to incorrect emission line strength estimates.

Table 3. The star formation rates of NGC 4676A and NGC 4676B estimated from CALIFA and multiwavelength observations.

Method	SFR _A /M _⊙ yr ⁻¹	SFR _B /M _⊙ yr ⁻¹
(H α ,H β) ^a	17-35	3-5
(H α ,mid-IR) ^b	4.3-6.9	1.3-2.1
stellar continuum ^c	2.6-5	1-4
(FUV,mid-IR) ^d	6.2	2.3
[Ne II] ^e	<10.1	<1.4
(FIR, radio) ^f	14	4

Notes. ^(a) Dust attenuation corrected H α luminosity using the Balmer decrement (Section 6.1). The errors on the dust attenuation correction in the nucleus of NGC 4676A are likely to be significant, due to the very high dust content. ^(b) Combination of H α and 24 μ m luminosities (Smith et al. 2007). ^(c) Decomposition of the stellar continuum using STARLIGHT (Section 5.3). ^(d) Combination of 24 μ m and FUV luminosities (Smith et al. 2010). ^(e) Mid-IR [Ne II] emission line (Haan et al. 2011). ^(f) Combined FIR and radio continuum luminosities (Yun & Hibbard 2001).

7. Multiwavelength analysis of global star formation rates

In the previous sections we have estimated the ongoing star formation rate of the Mice galaxies from both the ionised gas recombination lines and the stellar continuum in the CALIFA datacube, however, both estimates are uncertain. Although the higher SFR for NGC 4676A estimated from the emission lines compared to the stellar continuum may plausibly indicate a recent increase in SFR, we urge caution in this interpretation. A significant fraction of the line emission may arise from gas that has not been photoionised by stars, and the very large dust attenuation causes significant uncertainty in the central region of NGC 4676A. The SFR obtained from decomposition of the stellar continuum depends sensitively on the star formation history fitted by the STARLIGHT code. While both methods suggest that only moderate levels of star formation is ongoing in both galaxies, there are several multiwavelength observations that can be used to verify this result. These are summarised in Table 3 and discussed in more detail below.

The Mice have been observed in the mid-IR with the MIPS instrument on board Spitzer (Smith et al. 2007) and the NUV and FUV with GALEX (Smith et al. 2010). This provides us with two alternative SFR estimates which account for optically thick dust obscuration by direct detection of the thermal dust emission. Firstly, we combine the 24 μ m luminosity with the total H α line luminosity, using both the Calzetti et al. (2007) coefficient of 0.031 derived from H II regions and the Kennicutt et al. (2009) coefficient of 0.02 which includes a correction for diffuse emission. We note that this calibration depends on metallicity (e.g. Relaño et al. 2007), but is appropriate for the solar metallicity that we measure for the Mice galaxies in Section 6.2. This method results in a SFR of 4.3–6.9 M_⊙yr⁻¹ for NGC 4676A and 1.3–2.1 M_⊙yr⁻¹ for NGC 4676B, where the ranges account for the different coefficients and the upper and lower limits on the H α line flux that arises from H II regions.

We can combine the 24 μ m with the FUV luminosities to obtain a SFR independent of the CALIFA data, along with an attenuation in the FUV (A_{FUV}), following the prescription in Iglesias-Páramo et al. (2006)⁴. This results in a SFR of 6.2 M_⊙yr⁻¹, with an attenuation of $A_{\text{FUV}} = 3.3$ mag for NGC 4676A, and

SFR of 2.3 M_⊙yr⁻¹ with an attenuation of $A_{\text{FUV}} = 1.3$ mag for NGC 4676B.

We can use the [Ne II]12.81 μ m flux to provide a nebular line estimate of SFR that is unaffected by dust obscuration. Taking the [Ne II] flux reported in Haan et al. (2011) and the calibration of Diamond-Stanic et al. (2012) for galaxies with $L_{\text{IR}} < 10^{11}$ L_⊙, gives a SFR of <10.1 and <1.4 M_⊙yr⁻¹, for NGC 4676A and B respectively. The upper limits arise because, like H α , [Ne II] can be emitted by processes other than star-formation.

Finally, Yun & Hibbard (2001) combine FIR IRAS observations with radio continuum flux to estimate the FIR luminosity of each galaxy, even though they are not spatially resolved in IRAS. Assuming a factor of 2.5 conversion from Helou et al. (1988) to total infrared flux, and Kennicutt (1998b) conversion to SFR we obtain a SFR of 14 and 4 M_⊙yr⁻¹, for NGC 4676A and B respectively. Combining H α luminosity with our own estimate of IRAS total infrared flux from template fitting between 8–1000 μ m and the conversion given by Calzetti (2013) results in a lower total SFR for the two galaxies, but consistent within the scatter of the other measurements.

Given the complexity of the galaxies, it is perhaps surprising that the many different estimates of SFR are so close. Excluding the [Ne II] based estimate, for which we only have an upper limit, we obtain median values of 6.2 and 2.3 M_⊙yr⁻¹, for NGC 4676A and B respectively.

Dividing the total SFR of the galaxies by their stellar mass (Section 5.3) gives a specific SFR (sSFR) of 5×10^{-11} yr⁻¹ and 1.3×10^{-11} yr⁻¹ or log(sSFR/yr⁻¹) of -10.3 and -10.9 for NGC 4676A and B respectively.

8. The bicone in NGC 4676A

In Figure 9 we show two emission line diagnostic diagrams for individual spaxels in NGC 4676A. Spaxels in the disk are coloured blue and those in the bicones are coloured orange, with lightness of tone increasing with distance from the nucleus. While gas in the northern tidal tail and north and south disk shows line ratios similar to high metallicity star-forming galaxies in the local Universe (Kauffmann et al. 2003; Stasińska et al. 2006), the bicones have line ratios which indicate increasing hardness of the ionisation field with height above the mid-plane of the disk. At the outer extent the line ratios lie primarily in the region commonly occupied by Seyfert galaxies (Cid Fernandes et al. 2010; Kewley et al. 2006). Increasing hardness of the radiation field with distance from the mid-plane, and extended soft X-ray emission (Read 2003) is inconsistent with an AGN being the primary source of ionisation, but instead suggests that shocks driven by a superwind are ionising the gas (Heckman et al. 1990, hereafter HAM90).

Overplotted on Figure 9 are predictions from the fast-shock models of Allen et al. (2008)⁵, for a range of shock velocities (v_s) and magnetic field strengths (B). We use solar metallicity as measured from line ratios in the disk (Section 6.4), the abundance set of Grevesse et al. (2010) and a pre-shock density of 1 cm⁻³. In photoionising shocks, the flux of ionising radiation emitted by the shock increases proportional to v_s^3 , leading to a strong increase in pre-ionisation level of the gas as shock velocity increases. At the highest velocities, the ionisation front can expand ahead of the shock front, leading to an “ionised precur-

⁴ 24 μ m luminosities are converted to total IR luminosities (from 8 μ m to 1000 μ m) using the models by Chary & Elbaz (2001).

⁵ These were calculated using the ITERA package: (Groves & Allen 2010).

⁴ FUV luminosities are converted into SFRs using SB99 (Leitherer et al. 1999) and a Salpeter IMF with $M_{\text{low}} = 0.1$ M_⊙ and $M_{\text{up}} = 100$ M_⊙.

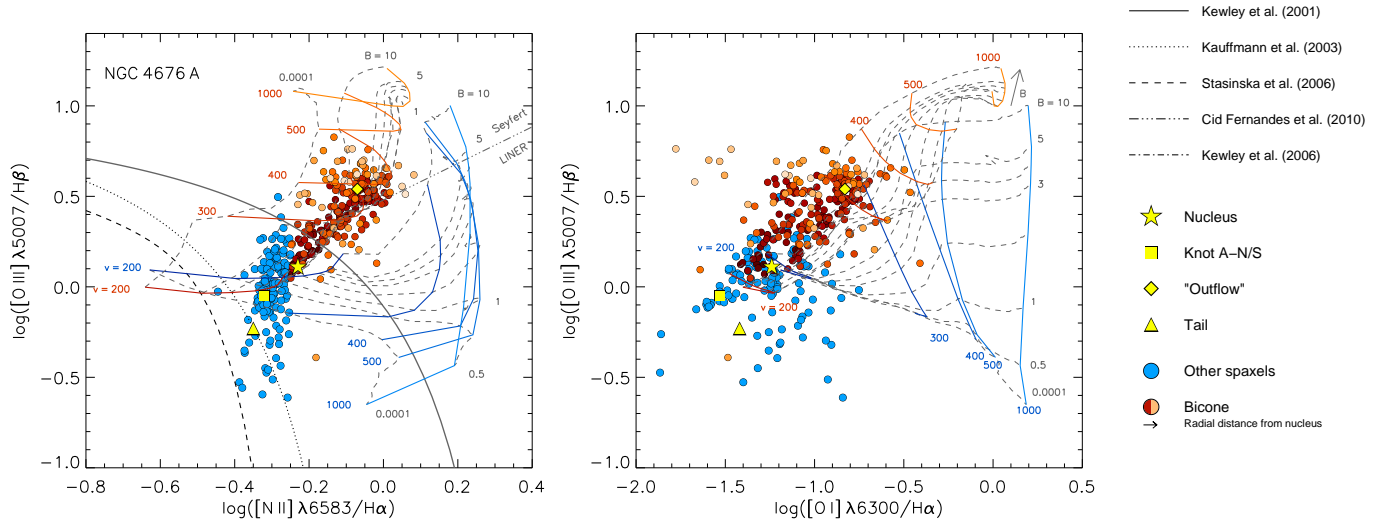

Fig. 9. Line ratio diagnostic diagrams, showing line ratios for independent spaxels in NGC 4676A. Those spaxels which lie in the bicones are coloured orange, shaded according to radial distance from the nucleus, the spaxels lying in the non-shocked regions are included as blue circles. Line ratios in some key regions of interest (see Fig. 2) are plotted as yellow symbols. Overplotted as black lines are empirically and theoretically derived separations between LINERs/Seyferts and H II regions. Overplotted as coloured lines are line ratios predicted for the photoionisation of gas by fast shocks from Allen et al. (2008), as described in the text. The blue model tracks show predicted line ratios when ionisation comes from the shock front alone, orange lines also include pre-ionisation by a precursor.

sor” which can contribute significantly to the optical emission of the shock. Magnetic fields can limit compression across the shock, thereby allowing the ionisation front to proceed into the post-shocked gas more quickly than the case with no magnetic fields, again leading to an increase in pre-ionisation level of the gas. We overplot predicted line ratios from models both with and without inclusion of the additional photoionisation caused by the precursor (orange and blue lines). The observed line ratios in the cone of NGC 4676A are consistent with a fast shock, including an ionised precursor, with velocity increasing from $\sim 200 \text{ km s}^{-1}$ in the centre of the galaxy to $\sim 350 \text{ km s}^{-1}$ at the outer edge of the bicone. We note that this apparent increase in shock velocity could also arise from a line-mixing scenario, where the emission from [H II] regions falls off more rapidly with height above the disk than emission from shocks. Further data would be needed to confirm whether or not the shock was increasing in velocity from the mid plane.

Recent low velocity shock models described in Rich et al. (2010, 2011) and Farage et al. (2010) are appropriate for shocks with velocities $\lesssim 200 \text{ km s}^{-1}$. As these models are not available, we compare to the figures published in Rich et al. (2011) for NGC 3256, which has a similar metallicity to NGC 4676A. We find that the large observed [O III]/H β line ratio in NGC 4676A is inconsistent with the slow shock models, and the closest models have velocities of $\lesssim 100 \text{ km s}^{-1}$, well below the measured velocity dispersion of the lines in the bicones.

8.1. Outflow kinematics

Shocks heat the gas through which they pass, and lead to increased linewidths of the post-shock emitting gas from thermal motions. Line splitting of absorption and/or emission lines is sometimes observed in galactic outflows, due to the bulk motions of gas towards and away from the observer. An increase in H α emission line width is observed in radial fingers extending along the minor axis of NGC 4676A (Figure 3), with a max-

imum velocity dispersion of $\sigma \sim 200 \text{ km s}^{-1}$. Unfortunately, with the limited spectral resolution of the CALIFA data we are unable to resolve the different kinematic components, thus we can only use the measured line widths to place limits on the bulk kinetic motions of the gas. If the increased linewidth is caused by bulk outflow, then the line-of-sight component of the outflow velocity is estimated from half of the full-width-half-maximum (FWHM) of the line to be $\sim 235 \text{ km s}^{-1}$. Including a significant tangential component, as might be expected from an outflowing wind, this is consistent with the estimate of the shock velocity estimated from line ratios above.

8.2. Energetics of the superwind fluid

Spatially resolved, optical line emission observations can constrain the rates at which the fast moving wind fluid in NGC 4676A carries mass, momentum and energy out of the galaxy. Within the context of the superwind model of HAM90, the wind in NGC 4676A has expanded beyond the initial “hot bubble” phase, into the “blow out” or free expansion phase, during which the wind propagates at approximately constant velocity into the intergalactic medium. The optical emission lines arise from clouds and wind shell fragments that are shock heated by the outflowing wind fluid.

The density of the medium into which the wind is propagating (n_1) can be determined from the electron density (n_e) measured from the [S II] line ratios (Section 6.3), combined with knowledge of the type of shock causing the optical line emission (see Appendix A for details):

$$n_1 [\text{cm}^{-3}] = 0.12 \left(\frac{n_e [\text{cm}^{-3}]}{100} \right) \left(\frac{350}{v_s [\text{km s}^{-1}]} \right)^2 \quad (1)$$

where v_s is the shock velocity. From this, the thermal pressure of the clouds where the [S II] emission arises is given by:

$$P_{\text{cloud}} = n_1 m_p \mu v_s^2 = 6.6 \times 10^{-11} \text{ Nm}^{-2} \quad (2)$$

where m_p is the proton mass, $\mu = 1.36$ accounts for an assumed 10% Helium number fraction and we have set $n_e = 200\text{cm}^{-3}$ from the observed [S II] line ratio at the outer extent of the bicones. We note that, for fast shocks, the thermal pressure of the cloud is independent of the shock velocity. This is equivalent to a pressure of $6.6 \times 10^{-10}\text{dynes cm}^{-2}$ or $P_{\text{cloud}}/k = 4.8 \times 10^6\text{K cm}^{-3}$. The pressure at the outer extent of the wind in NGC 4676A is a little larger than the range measured by HAM90 for 6 far-infrared galaxies (FIRGs) of $2.5 - 5 \times 10^{-10}\text{dynes cm}^{-2}$.

In the “blow-out” phase of a superwind, the pressure source in the outer regions of the wind is the ram pressure of the wind fluid itself⁶: $P_{\text{wind}} \sim P_{\text{cloud}}$. This allows us to use the information derived from the shock heated gas to determine the momentum flux of the wind flowing into a solid angle Ω . Following HAM90:

$$\dot{p}_{\text{wind}} = P_{\text{wind}}(r)r^2 \frac{\Omega}{4\pi} = 1.3 \times 10^{30}\text{N} \quad (3)$$

where $P_{\text{wind}}(r)$ is the wind pressure at radius r and we have estimated $r = 6.6\text{kpc}$ and $\Omega/4\pi \sim 0.37$ from the CALIFA maps. This is equivalent to $1.3 \times 10^{35}\text{dynes}$. This compares to values ranging from $0.3 - 12 \times 10^{35}\text{dynes}$ for the winds in HAM90, although we note that these will be upper limits, as without IFS data the authors assumed $\Omega/4\pi = 1$.

Both the energy and mass outflow rates can be estimated from the momentum flux, however, they depend upon the unknown velocity of the wind fluid. For typical values for superwinds of $v_w = 1000 - 3000\text{km s}^{-1}$ (Hopkins et al. 2013; Seaquist et al. 1985, HAM90) we estimate a total energy flux of

$$\dot{E}_{\text{wind}} = 0.5 P_{\text{wind}} r^2 v_w \frac{\Omega}{4\pi} = [6.4 - 20.4] \times 10^{42}\text{erg s}^{-1} \quad (4)$$

and a mass outflow rate of

$$\dot{M}_{\text{wind}} = \frac{P_{\text{wind}} r^2}{v_w} \frac{\Omega}{4\pi} = [8 - 20]\text{M}_{\odot}\text{yr}^{-1}. \quad (5)$$

This mass outflow rate is a factor of 1.5-3 larger than the global star formation rate of the galaxy ($\dot{M}^* \sim 6\text{M}_{\odot}\text{yr}^{-1}$, Section 7), which is typical for galaxy outflows (e.g. Martin 1999; Veilleux et al. 2005).

8.3. The optical emission nebulae

Given the LINER- and Seyfert-like line ratios observed in the bicones, the optical line emission seen at large distances from the galaxy must largely be a direct result of the fast, radiative shocks which are being driven into the ambient medium by the superwind.

To obtain the total dust attenuation corrected H α luminosity⁷ in the bicones we sum over regions with $\log([\text{N II}]/\text{H}\alpha) > -0.25$ and conservatively exclude emission within 1.3 kpc ($3''$) of the

⁶ A lower limit on the ram pressure of the wind fluid can also be estimated from the X-ray data. Taking the density and temperature from Read (2003) we find $P/k > 1 \times 10^5\text{K cm}^{-3}$, consistent with the CALIFA results. However, we note that this value is highly uncertain: the lack of counts in the X-ray data have deterred other authors from fitting the X-ray spectrum to obtain a temperature (González-Martín et al. 2009). Improved X-ray data would be required to estimate a filling factor for the X-ray emitting gas.

⁷ Where H β is not measured we use uncorrected H α line luminosities, although this is only the case in the fainter outer regions and makes no difference to the final results.

nucleus, where the [N II]/H α line ratio lies in the composite region of the BPT diagram and we might expect a significant fraction of line emission to instead arise from photoionisation by stars in the starburst. We also exclude the highly ionised gas to the north and south of the nucleus, as this may have a different origin. We find the total H α luminosity of the nebulae is $L_{\text{neb}} = 7 \times 10^{41}\text{erg s}^{-1}$, leading to a bolometric energy loss rate of $\dot{E}_{\text{neb}} \sim 5.5 \times 10^{43}\text{erg s}^{-1}$, where we have assumed a bolometric conversion factor of 80, appropriate for ionisation by shocks with $v_s \gtrsim 140\text{km s}^{-1}$ (Rich et al. 2010). This is a factor of 2-6 larger than the energy flux in the wind fluid estimated from the geometry and cloud pressure (\dot{E}_{wind} , Equation 4). Given the uncertainties in the many assumptions made to obtain these two numbers, we consider them to be in good agreement, implying a near 100% efficiency in converting wind energy into radiation. However, it is possible that an additional source of ionisation is contributing to the optical nebulae, or our zeroth order calculations have underestimated the energy flux of the wind by a factor of a few. In comparison, HAM90 find the total dust attenuation corrected line luminosity in FIRGs to range from $1.5 \times 10^{42} - 1.5 \times 10^{44}$, assuming a bolometric correction of 30. They also note that $\dot{E}_{\text{wind}} \approx L_{\text{neb}}$ implies a high efficiency for converting the wind energy into emission lines.

From the optical emission flux we can also estimate the total mass of ionised gas currently decelerating at the shock fronts:

$$M_{\text{ion}} = \frac{\mu m_p L_{\text{H}\alpha,0}}{\gamma_{\text{H}\alpha}(T)n_e} \quad (6)$$

where, for Case B recombination and purely photoionised gas of electron temperature T , the effective volume emissivity is $\gamma_{\text{H}\alpha}(T) = 3.56 \times 10^{-25} T_4^{-0.91}\text{erg cm}^{-3}\text{s}^{-1}$ ($T_4 = T/10^4\text{K}$). Taking $T = 10^4$ and the median electron density throughout the bicones of $n_e = 400\text{cm}^{-3}$ we find a total ionised gas mass of $\sim 6 \times 10^6\text{M}_{\odot}$.

For a shock front travelling at 350km s^{-1} the crossing time to reach the outer edge of the bicones is $\sim 18\text{Myr}$. Assuming the shocks cause a bulk motion of the entrained gas at the velocity of the shock, this gives an ionised gas mass outflow rate of $0.3\text{M}_{\odot}\text{yr}^{-1}$. We see that the mass of outflowing ionised gas is negligible compared to the total mass in the wind (Eqn. 5).

8.4. Comparison to the energy injection rate by SNe

The mechanical energy injection rate into the ISM by supernovae (SNe) and stellar winds can be estimated from evolutionary synthesis models of populations of massive stars (Leitherer et al. 1999; Veilleux et al. 2005):

$$\dot{E}_* = 7 \times 10^{41} \left(\frac{\text{SFR}}{\text{M}_{\odot}\text{yr}^{-1}} \right) = 4.3 \times 10^{42}\text{erg s}^{-1} \quad (7)$$

for $\text{SFR} = 6.2\text{M}_{\odot}\text{yr}^{-1}$ (Section 7), and we have taken the limiting assumption that the mechanical energy from all of the stars being formed throughout the entire galaxy is available to drive the wind. Even under this assumption, this barely provides sufficient energy to drive the lowest velocity wind assumed above, and is a factor of 10 too little to power the emission line nebulae. The geometry of the outflow as seen in the CALIFA observations suggests that only the central star formation is driving the wind, increasing the discrepancy. This implies that other forms of energy injection into the biconical nebulae are required beyond simple mechanical energy, such as photo-heating from the young stars and radiation pressure (see e.g. Hopkins et al. 2013 for recent simulations including these effects).

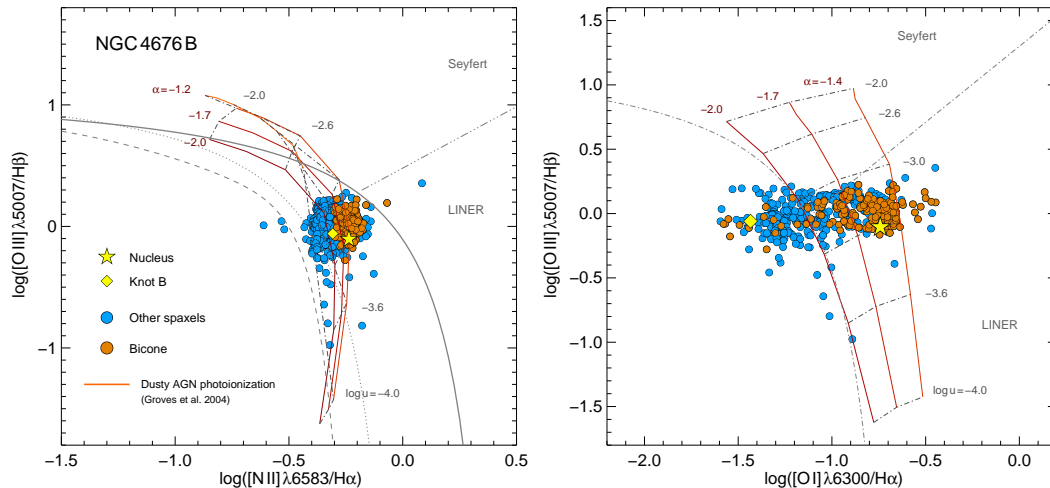

Fig. 10. Line ratio diagnostic diagrams, showing line ratios for independent spaxels in NGC 4676B. Those spaxels which lie in the bicones are coloured orange, the remainder of the spaxels are included as blue circles. Line ratios in some key regions of interest are shown as yellow symbols (see Fig. 2). Overplotted as black lines are empirically and theoretically derived separations between LINERs/Seyferts and H II regions, as given in Figure 9. Overplotted as coloured lines are AGN photoionisation model predictions by Groves et al. (2004).

9. The bicone in NGC 4676B

A bicone is also evident in the line ratio maps of NGC 4676B (Figure 7). The different pattern of line ratios to those seen in NGC 4676A suggest that different physical mechanisms are responsible. In Figure 10 we plot two emission line diagnostic diagrams for individual spaxels in NGC 4676B. As seen in the map, the bicone does not have distinct [O III]/H β line ratios compared to the disk. The nucleus has line ratios in the “composite” region in [N II]/H α , and in the LINER region in [O I]/H α .

The hard X-ray detection, compact distribution of soft X-rays and unusually high ratio of mid-IR excited H $_2$ emission to PAH emission suggest an AGN may be present in NGC 4676B (González-Martín et al. 2009; Masegosa et al. 2011; Read 2003, see Section 1). If so, the AGN is weak, with a hard X-ray luminosity of $L_{X,2-10\text{keV}} = 1.48 \times 10^{40} \text{erg s}^{-1}$. Using a bolometric conversion factor of 50 suitable for LINERs (Eracleous et al. 2010b), results in a bolometric luminosity of $7.4 \times 10^{41} \text{erg s}^{-1}$ or $\log(L/L_\odot) = 8.3$, typical for LINER galaxies. From the CALIFA nuclear spectrum we measure an [O III] luminosity of $\log(L_{\text{OIII}}/L_\odot) = 5.9$. Using a bolometric conversion factor of 600 (Heckman et al. 2004), leads to a bolometric luminosity of $1.7 \times 10^{42} \text{erg s}^{-1}$ or $\log(L/L_\odot) = 8.7$. Given the errors inherent in these conversions, these values are consistent.

Predicted line ratios from the AGN photoionisation models of Groves et al. (2004) are overplotted in Figure 10, for a range of dimensionless ionisation parameter ($u \equiv q/c$) and spectral index (α). The line ratios in the nucleus are consistent with an AGN with $\log u \sim -3.3$ and $\alpha \sim -1.5$, with line mixing from [H II] regions in the host galaxy disk causing the variation across the galaxy. It is also worth considering the potential of post-AGB stars in the underlying old stellar population to contribute to the ionising photon field, particularly in the massive bulge of NGC 4676B (see e.g. Eracleous et al. 2010a). However, the observed H α equivalent width in the nucleus of NGC 4676B is $\sim 25\text{\AA}$, which firmly rules out any significant contribution to the line emission from post-AGB stars (Cid Fernandes et al. 2011). Finally, the nuclear line ratios are also consistent with slow-shock models including some line mixing from low level star formation (e.g. Rich et al. 2011). Ultimately, understanding fully the source of the high ionisation lines in NGC 4676B

Fig. 11. The combined SFR of the mock Mice over the duration of the merger simulation. The blue and red vertical marks indicate the time of first passage and time of observation at 180 Myr after first passage.

will require observations with higher SNR, spatial and spectral resolution.

10. Comparison to simulations

Since the initial galaxy merger simulations by Toomre & Toomre (1972), a large research effort has focussed upon trying to reproduce the spatial distribution of stars, gas, star formation and stellar cluster ages in mergers (e.g. Karl et al. 2010; Lanz et al. 2014). With their tidal tails constraining the orbital parameters reasonably well, the Mice have been an obvious target for such studies. For example, Mihos et al. (1993) found the SFR of NGC 4676A to be higher in models than data, which could result from limitations of the data available at the time (e.g. inability to correct for dust attenuation) or limitations of the model. Barnes (2004) used the Mice as a case study to advocate a shock-induced star formation law, rather than the standard gas density driven star formation implemented in hydrodynamic simulations (see also Teyssier et al. 2010). Recently, Privon et al. (2013) presented a new solution for the orbital parameters of the Mice from purely N-body simulations, which differ from those of Barnes (2004), largely due to the use of a different mass model for the galaxies. The degeneracy between mass model and orbital pa-

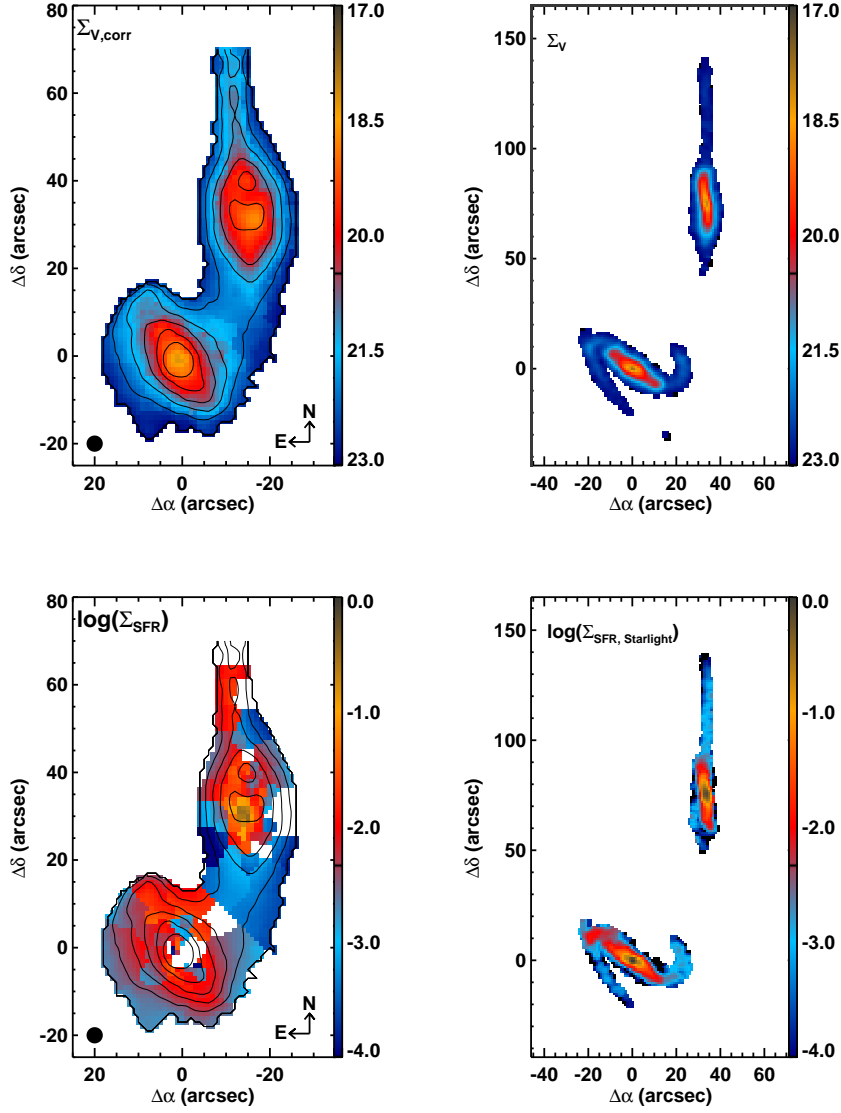

Fig. 12. *Top:* The V-band surface brightness ($\text{mag}/\text{arcsec}^2$) of the real (*left*) and mock (*right*) Mice. The surface brightness of the real Mice has been corrected for dust attenuation using the analysis from the STARLIGHT code (Section 5). The surface brightness of the mock Mice has been calculated by post-processing an SPH simulation to obtain a mock IFU datacube with the same spectral range and resolution as the CALIFA data. This has been analysed using the same pipelines as the real data. *Bottom:* The star formation rate surface density ($\text{M}_\odot \text{yr}^{-1} \text{kpc}^{-2}$) measured from the stellar continuum using the STARLIGHT code, averaged over the last 140 Myr, for the real (*left*) and mock (*right*) Mice. White indicates regions with no measurable star formation.

rameters are discussed in detail in Privon et al. (2013) and inhibit easy comparison between simulations and observations.

With observations advancing towards an era in which spatially resolved star formation histories, kinematics, ionisation mechanisms and AGN strengths are well constrained for single objects, simulations are facing more stringent observational constraints than ever before (e.g. Kronberger et al. 2007). Given the primarily observational nature of this paper, we present here an illustrative, rather than exhaustive, comparison of the CALIFA results with a standard smoothed particle hydrodynamic (SPH) merger simulation. It is simulations such as these that have driven many of the currently favoured models of galaxy evolution over the last decade, and it is worth investigating how well they match the latest generation of observations. For conciseness, we focus on the stellar kinematics, SFR surface densities

and star formation histories of the galaxies, leaving a more complete study for further work.

The simulation represents the collision of two galaxies with a baryonic mass ratio of 1.3: a pure exponential disk galaxy and a galaxy with a bulge-to-disk ratio of 0.27. These parameters are very close to the observed mass ratio and morphologies of the Mice galaxies. We take the orbital parameters provided in Barnes (2004), i.e. a close to prograde-prograde orbit with a closest approach of $\sim 10 \text{ kpc}$ occurring $\sim 170 \text{ Myr}$ ago. Star formation and the associated supernova feedback is implemented using the sub-resolution multiphase model developed by Springel & Hernquist (2003), in which cold gas forms stars when its density reaches above a certain density threshold ($n_{\text{H}} = 0.128 \text{ cm}^{-3}$, appropriate for the resolution of the simulation). For the purposes of this CALIFA comparison, black hole feedback is not included.

Fig. 13. The stellar velocity field and dispersion of the mock Mice. See Figure 3 to compare with the data.

Spectral energy distributions of each of the star particles were calculated from their star formation history, using the models of Bruzual & Charlot (2003). In order to make a fair comparison between observations and simulations, we convert the simulation into an IFS data cube with the same spectral and spatial resolution as the data, and analyse this cube using the same codes as employed on the real data. Full details of the simulations and post-processing applied to produce the mock observations are given in Appendix B.

Figure 11 presents the global SFR of both galaxies in the simulation, over the full 3 Gyr run-time. The time of first passage and time of observation are marked as vertical lines. The small burst of star formation caused by first passage is evident. At final coalescence the simulations predict a $40\text{--}50\text{M}_{\odot}\text{yr}^{-1}$ starburst; however, more accurate gas mass fractions of the real Mice would be required to improve the accuracy of this prediction.

The upper panels of Figure 12 show maps of the V-band surface brightness of the real and mock Mice. The data has been corrected for dust extinction using the V-band stellar continuum attenuation map estimated by the STARLIGHT code. On altering the viewing angle of the simulation a strong bar becomes visible in NGC 4676A. This lends support to our argument that the boxy shape of NGC 4676A is caused by an edge-on bar rather than a classical bulge (Section 4.1). While the sizes and overall surface brightnesses of the real and mock galaxies are largely comparable, the mock galaxies are separated by a distance on the sky that is a factor of 2 larger than observed. This may result from incorrect initial orientations, orbits, mass profiles, or shapes of the dark matter halo. The new orbital parameters presented in Privon et al. (2013) differ in several aspects to those used here. However, because these authors assume very different mass models for the progenitor galaxies, their orbital parameters are no more likely to provide a better match. Simply slowing the initial velocities of the simulated galaxies resulted in too short tidal tails, and further investigations into the origin of the discrepancy are beyond the scope of this primarily observational paper.

The lower panels of Figure 12 show the SFR surface density averaged over the last 140 Myr, calculated for both the real and mock Mice from the decomposition of the stellar continuum by the STARLIGHT code (Section 5). The SFR surface den-

sity reconstructed from the mock IFS data cube using STARLIGHT closely matches the instantaneous SFR surface density taken directly from the simulation. The global SFR of each of the mock galaxies is $\sim 2.5\text{M}_{\odot}\text{yr}^{-1}$, in agreement with the observed SFR for NGC 4676B ($2\text{M}_{\odot}\text{yr}^{-1}$) and a little lower than observed for NGC 4676A ($6\text{M}_{\odot}\text{yr}^{-1}$).

The SFR surface densities in the central $5 \times 5''$ (2.2 kpc) are $\sim 0.3\text{M}_{\odot}\text{yr}^{-1}\text{kpc}^{-2}$ for both mock galaxies. The value averaged over 140 Myr using the STARLIGHT spectral decomposition is close to the instantaneous value obtained directly from the simulation. This compares well to a central SFR density of $0.15\text{M}_{\odot}\text{yr}^{-1}\text{kpc}^{-2}$ for NGC 4676A and is not substantially different from the $\sim 0\text{M}_{\odot}\text{yr}^{-1}\text{kpc}^{-2}$ measured for NGC 4676B from the STARLIGHT spectral decomposition (Section 5). However, the observed decrease in SFR surface density towards the central regions of NGC 4676B is not reproduced by the simulations.

Figure 13 shows the stellar velocity field and velocity dispersion maps of the mock Mice. The velocity map of NGC 4676A is a good match to the data, and including a bulge results in a significantly worse match. The velocity map of NGC 4676B is dominated by a rotating disk, with the bulge causing the pinched effect at the centre and small rise in velocity dispersion. The unusual twisted stellar disk velocity field seen in the observations, with the rotation axis offset from the minor axis, is not observed at this stage of the simulation. During the full run time of the simulation, the high surface brightness of the tidal tails in the Mice is clearly a transient feature. There is also evidence for a slight twist in the velocity field of NGC 4676B at some epochs of the simulations, similar to that seen in the observations. Precisely reproducing these transient morphological and kinematic features may make it possible to set tighter constraints on the orbital parameters of the Mice merger and mass distribution of the galaxies in the future.

11. Discussion and Summary

Here we summarise the impact of the close encounter on the morphology, kinematics, star formation rate and history, and

Table 4. A summary of the main properties of the Mice galaxies measured in this paper. For a summary of properties available from the literature see Table 1.

Parameter	NGC 4676A (NW)	NGC 4676B (SE)
B/T ^a	0 (SBd)	0.5 (S0/a)
$v_{\text{nucleus,gas}}$ (km/s) ^b	6585	6581
$v_{\text{nucleus,stars}}$ (km/s) ^b	6652	6493
M^* ($10^{11} M_{\odot}$) ^c	1.2	1.5
SFR (M_{\odot}/yr) ^d	~ 6	~ 2
P/k_{wind} (10^6K cm^{-3}) ^e	4.8	...
\dot{M}_{out} ($M_{\odot} \text{yr}^{-1}$) ^e	8-20	...
Morphological PA ^f	2.8	33.2
Kinematic PA _{stars} ^f	33.9, 27.6	165.4, 150.4
Kinematic PA _{gas} ^f	31.9, 24.5	154.4, 165.0

ionised gas of the merging galaxies. Table 4 collates some of the key properties measured in this paper.

1. Merger induced bars in NGC 4676B and NGC 4676A?

The strong bar in NGC 4676B is clear, both in the image and kinematics maps: the characteristic Z-shaped iso-velocity contours are visible in both the ionised gas and, unusually, in the stellar velocity field. While NGC 4676A has previously been classified as an S0, the CALIFA maps of the stellar kinematics show no evidence for a classical bulge, with low nuclear velocity dispersion and constant rotation above with height above the major axis. A young, thin, disk is visible in the stellar population maps, with older populations extending into the “boxy” shaped bulge. The high dust and gas content of the galaxy is also inconsistent with its classification as an S0. It is possible that the boxy morphology evident in the imaging (See Figure 1) comes from a strong bar (e.g. Bureau & Athanassoula 1999, 2005; Kuijken & Merrifield 1995; Martínez-Valpuesta et al. 2006; Williams et al. 2011); further detailed investigation of higher order moments in the velocity map may help to confirm this. The first passage of a major merger is seen to induce strong bars in simulations of disk galaxies (e.g. Barnes & Hernquist 1991; Lang et al. 2014), including the mock Mice simulation presented here. While we cannot rule out the pre-existence of bars in the merging galaxies, the presence of such strong bars in both galaxies, combined with predictions from simulations, suggests that these have been induced by the recent close encounter.

2. **Z-shaped stellar velocity field in NGC 4676B.** The CALIFA data reveals that the dominant rotation of both the ionised gas and stars in NGC 4676B is close to being around the major axis of the galaxy (offset between morphological and kinematic PAs of 50-60 degrees). While these Z-shaped (or S-shaped) isovelocity contours are a common feature in the gas velocity fields of strongly barred galaxies (e.g. Contopoulos & Papayannopoulos 1980), and weak warps can be

seen in the outer regions of stellar disks (Saha et al. 2009), such strong disturbance of the inner stellar velocity field is unusual (for one other example see NGC 4064, Cortés et al. 2006). Barrera-Ballesteros et al. (2014) have confirmed that bars have no significant effect on stellar velocity fields in the full CALIFA sample. Studies of larger samples are needed to see whether such strong twists are common in merging galaxies (see Barrera-Ballesteros et al. in prep., for such a study within CALIFA).

3. **No substantial increase in global star formation rates.** We can compare the sSFR of the Mice galaxies to the distribution of aperture corrected sSFR as a function of stellar mass for galaxies in the SDSS survey (Figure 24 of Brinchmann et al. 2004). We find that NGC 4676A lies at the upper end of stellar masses measured for star-forming galaxies in the local Universe and has exactly typical sSFR for its stellar mass. NGC 4676B has a slightly low sSFR for its stellar mass, but still lies well within the range observed in the general population. Both galaxies have SFR surface densities typical of star-forming disk galaxies. We conclude that there is no evidence that either galaxy is currently undergoing a substantial galaxy-wide burst of star formation. These results are broadly consistent with the mock Mice simulations, where the galaxies have only undergone a small increase in global SFR since first passage. Circumstantial evidence for increased star formation in close pairs has existed for decades (e.g. Bernloehr 1993). Statistically significant evidence for the enhancement in star formation due to interactions and mergers has come from large samples of spectroscopically observed galaxies in the last decade (Barton et al. 2000; Lambas et al. 2003; Patton et al. 2011, 2013; Woods et al. 2010). Estimates of the occurrence, strength and duration of SFR enhancement vary. For example, Woods et al. (2010) find that SFR increases by a modest factor of 2-3 averaged over the duration of the enhancement, which is around a few hundred million years. Such enhancements occur in about 35% of close pairs. These observational results are consistent with hydrodynamic galaxy merger models (Matteo et al. 2008) and show that the lack of SFR enhancement in the Mice galaxies is not unexpected.

4. **No substantial post-starburst population.** First passage of the Mice merger occurred roughly 170 Myr ago (Barnes 2004; Chien et al. 2007) and star formation induced at this epoch should be identifiable through decomposition of the stellar continuum to measure the fraction of light from A and F stars. Referring to the fraction of light emitted by stars formed between 140 Myr and 1.4 Gyr ago in Figure 5, we see that during this time star formation is located primarily in the disks of both galaxies, as expected for continuous star formation histories. There is some enhancement in the intermediate age population in the outer extents of the galaxies. Our results show that, while some low level star formation at large radii may have been triggered by the first passage, the fraction of total stellar mass formed was not significant.

5. **Weak nuclear starburst in NGC 4676A.** Due to the attenuation by dust in the centre of NGC 4676A, and poor spatial resolution of far infrared observations, our estimates of the nuclear SFR are uncertain. The SFR surface density in the central $\sim 5''$ estimated from the STARLIGHT spectral decomposition is $\sim 0.15 M_{\odot} \text{yr}^{-1} \text{kpc}^{-2}$, placing it at the upper end of the range for local spiral galaxies (Kennicutt 1998a). This is in good agreement with the mock Mice simulation.

6. **No ongoing star formation in the centre of NGC 4676B.** Our stellar continuum decomposition of NGC 4676B shows

a complete absence of young stars within ~ 1 kpc of the nucleus (Figure 5). The upper limit on the SFR surface density from the dust attenuation corrected $H\alpha$ luminosity is $\Sigma_{SFR} < 0.2 M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$ within the central $5''$. It is clear that NGC 4676B is not currently undergoing or has not recently undergone a nuclear starburst. The strong bar has not yet driven significant gas into the nucleus. This decrease in SFR surface density in the central regions of the galaxy is not reproduced by the mock Mice simulation.

7. Spectacular bicones driven by fast shocks in NGC 4676A.

The extreme line ratios seen at the outer edge of the bicones are consistent with being caused by fast shocks ($v_s \sim 350 \text{ km s}^{-1}$) driven by a superwind. The emission of NGC 4676A in soft X-rays is also found to be elongated along the minor axis of the galaxy, coincident with the ionised gas bicones seen here (Read 2003), again implying a strong galactic outflow. In the nearby Universe observational studies of galactic superwinds have focussed primarily on LIRGs and ULIRGs, where a clear driving source is present (see Veilleux et al. 2005, for a review). As NGC 4676A is less luminous than a LIRG, and has a moderate star formation rate despite its very large mass, it would not have been an obvious candidate for superwind investigations. Stacking of rest-frame optical and UV spectra finds evidence for winds in a large fraction of star forming galaxies at all redshifts (e.g. Chen et al. 2010; Weiner et al. 2009), implying that our census of superwinds is still far from complete and NGC 4676A may not be so unusual. Many more outflows may be found in ongoing and upcoming IFU galaxy surveys (e.g. Fogarty et al. 2012, in commissioning data for the SAMI survey).

8. What drives the outflow in NGC 4676A? Observational results suggest a minimum SFR surface density of $\sim \Sigma_{SFR} = 0.1 M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-2}$ is required for superwinds to be launched from galaxies in the local and distant Universe (Heckman 2002, and see the recent compilation by Diamond-Stanic et al. 2012). Thus, although the nuclear starburst in NGC 4676A is not significant in terms of global SFR and is weak with respect to local starbursts, it is powerful enough to launch a wind in principle. The mass outflow rate from NGC 4676A is about 1.5-3 times the global SFR of the galaxy, which is typical for galactic outflows in the local Universe (Martin 1999). On the limiting assumption that the star formation in the entire galaxy is driving the superwind, we show that the mechanical energy available from SNe and stellar winds is a factor of 10 too low to explain the optical line emission in the bicones above 1.3 kpc from the plane of the galaxy, and only sufficient to explain the energy outflow rate if the velocity of the wind fluid is very low ($< 1000 \text{ km s}^{-1}$). If only the nuclear star formation is driving the wind, as suggested by the CALIFA maps, the discrepancy increases. Additional sources of energy input could be from ionising photons and radiation feedback (Agertz et al. 2013; Hopkins et al. 2013; Murray et al. 2011). Alternatively, the additional energy could have been provided by a source that has since switched-off, such as an AGN or a more intense starburst at first passage.

9. Extended narrow line region (ENLR) in NGC 4676B. The kiloparsec scale bicones in NGC 4676B are not accompanied by higher velocity dispersion gas, and the line ratios are consistent with ionisation by an AGN. The detection of hard X-rays in the nucleus and point source like distribution of soft X-rays suggests the presence of a weak AGN. We conclude that there is no evidence for a galactic outflow

from NGC 4676B (as seen in e.g. Cen A, Sharp & Bland-Hawthorn 2010), and the bicones are more likely caused by the excitation of off-planer gas by an AGN (as seen in e.g. NGC 5252, Morse et al. 1998). Kiloparsec scale ENLRs are not unusual in local AGN (Geressen et al. 2012).

10. Areas for improvement in the simulations. The new constraints afforded by the CALIFA data of the Mice galaxies indicate new directions where improvements can be made in the simulations. Firstly, there is some tension between the geometry of the tidal tails and the relative position of the two Mice, with the simulation Mice flying twice as far apart to obtain the same length and surface brightness of the tails. Further useful constraints on the orbital parameters of the merger and mass profiles of the galaxies may be obtained by detailed matching of transient morphological and kinematic features, such as the twist in the disk of NGC 4676B, the orientation of the two bars and the surface brightness of the tidal tails. Secondly, observations of the gas mass fraction of the galaxies could be used to further test the ability of the models to reproduce the SFR surface density maps, and in particular understand the very low star formation rate observed in the nucleus of NGC 4676B.

12. The future is a LIRG... and then?

While the combination of CALIFA and multiwavelength data has conclusively shown that first passage has not triggered substantial star formation, the considerable gas content of the two galaxies makes it likely that final coalescence will cause a substantial starburst. The two galaxies have a combined molecular gas mass of $7.2 \times 10^9 M_{\odot}$ (Yun & Hibbard 2001), which on conversion to stars will lead to a SFR of order $100 M_{\odot} \text{ yr}^{-1}$ over a timescale of 10^7 years and efficiency of 10% (or timescale of 10^8 years and efficiency of 100%), values typical for starburst galaxies (Kennicutt 1998a). This would result in an $8\text{-}1000 \mu\text{m}$ luminosity of $L_{IR} \sim 5 \times 10^{11} L_{\odot}$, i.e. a LIRG. The simulation presented in Section 10 predicts a similar peak SFR of $\sim 50 M_{\odot} \text{ yr}^{-1}$.

On coalescence the galaxy will have a stellar mass of $\sim 3 \times 10^{11} M_{\odot}$ (Salpeter IMF), assuming that each galaxy increases its mass by 10% during the starburst as found observationally (Robaina et al. 2009; Wild et al. 2009). Converting to a Chabrier IMF ($1.8 \times 10^{11} M_{\odot}$) and comparing to the galaxy mass function of Baldry et al. (2012) we see that this places the merger remnant in the very highest mass galaxy population in the local Universe. Galaxies of this mass and above have a number density of a few $\times 10^{-4} \text{ Mpc}^{-3}$.

Extending the predictions for the properties of the system beyond coalescence of the galaxies requires input from simulations. By the end of the hydrodynamic merger simulation presented in Section 10, in about 2.2 Gyr time, the merger remnant will have a SFR of $1 M_{\odot} \text{ yr}^{-1}$, with the decay in star formation occurring as a natural result of gas consumption. This would lead to an elliptical galaxy with a specific star formation rate (SFR/ M^*) of $5 \times 10^{-12} \text{ yr}^{-1}$, within the range measured for galaxies of this mass in the local Universe (Schiminovich et al. 2007).

Acknowledgements

This study makes use of the data provided by the Calar Alto Legacy Integral Field Area (CALIFA) survey (<http://www.califa.caha.es>). Based on observations collected at the Centro Astronómico Hispano Alemán (CAHA) at Calar Alto, operated jointly by the Max-Planck-Institut für Astronomie and the Instituto de Astrofísica de Andalucía (CSIC).

CALIFA is the first legacy survey being performed at Calar Alto. The CALIFA collaboration would like to thank the IAA-CSIC and MPIA-MPG as major partners of the observatory, and CAHA itself, for the unique access to telescope time and support in manpower and infrastructures. The CALIFA collaboration thanks also the CAHA staff for the dedication to this project.

The authors would like to thank the anonymous referee for comments that significantly improved the paper; Dimitri Gadotti for providing extensive help and advice with the image decomposition; Mike Dopita and Tim Heckman for their patience explaining the effects of shocks in superwinds; Daria Dubinovska for creating undistorted ACS PSF images from the Tiny Tim images and Carolin Villforth for further help with the ACS PSF; Lia Athanassoula for help interpreting the kinematic maps; Daniel Pomaredé for help getting SDvision running; Jeremy Sanders and Roderik Johnstone for help interpreting the X-ray observations; Eva Schinnerer for pointing out the effect of beam smearing; all other interested researchers who have contributed with questions and comments following discussions and presentations of this work over the last 2 years.

The numerical simulations were performed on facilities hosted by the CSC -IT Center for Science in Espoo, Finland, which are financed by the Finnish ministry of education.

Appendix A: Pre- and post-shock gas density

Assuming pressure equilibrium between the post-shock gas and the gas that has cooled sufficiently to emit [S II], the CALIFA observations can be used to measure the pre-shock density (n_1) in the following way. The post-shock temperature (T_2) is given by

$$T_2[K] = 1.38 \times 10^5 \left(\frac{v_s[\text{km/s}]}{100} \right)^2 \quad (\text{A.1})$$

for a fully ionised precursor (Dopita & Sutherland 2003). The temperature of the gas emitting [S II] is $T_3 \sim 8000$ K, and the density of this gas is measured from the [S II] line ratio ($n_3 = n_e$). For a fast shock the post-shock density is four times the pre-shock density ($n_2 = 4n_1$). The pre-shock gas density is then given by:

$$n_1[\text{cm}^{-3}] = \frac{n_3 T_3}{4 T_2} = 0.12 \frac{n_e[\text{cm}^{-3}]}{100} \left(\frac{350}{v_s[\text{km/s}]} \right)^2 \quad (\text{A.2})$$

From this, we can estimate the thermal pressure of the clouds where the [S II] lines are produced:

$$P_{\text{cloud}} = \rho_1 v_s^2 = n_1 m_p \mu v_s^2 \quad (\text{A.3})$$

where ρ_1 is the mass density of the medium into which the shock is propagating, v_s is the shock velocity, m_p is the proton mass, $\mu = 1.36$ accounts for an assumed 10% Helium fraction. This gives a relation between thermal pressure and electron density

$$P_{\text{cloud}} = 3.3 \times 10^{-11} \frac{n_e[\text{cm}^{-3}]}{100} \text{Nm}^{-2} = 3.3 \times 10^{-12} n_e \text{dynes cm}^{-2} \quad (\text{A.4})$$

close to the value given by HAM90 of $4 \times 10^{-12} n_e \text{dynes cm}^{-2}$ based on shock models by Shull & McKay (1985).

The bolometric luminosity per unit area of a shock can be independently estimated from $\mathcal{L}_{\text{shock}} = 0.5 \rho v_s^3$, and this provides a consistency check on the shock speed estimated from the model fit to the observed line ratios. Summing over the full area of the two bicones, which we estimate from the CALIFA maps to cover 1/4 of a sphere, we find a bolometric energy loss rate of $\dot{E}_{\text{shock}} = 3.2 \times 10^{43} \text{erg s}^{-1}$ for $v_s = 350 \text{km s}^{-1}$. This is only a factor of ~ 2 smaller than the estimated bolometric luminosity of the bicones, which lies well within the errors of these calculations, and supports the argument that 350km s^{-1} fast shocks are the most likely candidate for causing the ionisation of the gas in the cones.

Appendix B: Simulation methodology

The details of the simulation are presented in Johansson et al. (2009b) and Johansson et al. (2009a), here we provide a brief summary of the relevant details. The simulations were performed using the entropy conserving TreeSPH-code GADGET-2

(Springel 2005) which includes radiative cooling for a primordial mixture of hydrogen and helium together with a spatially uniform time-independent local UV background.

The assumed dark matter profile has a significant impact on the evolution of the merger. Here we use an “NFW-like” profile, i.e. an analytical Hernquist (1990) dark matter profile, with a concentration parameter $c = 9$, matched to the empirical Navarro et al. (1996) profile as described in Springel et al. (2005). Disks have exponential profiles, with a total baryonic disk mass of $M_d = m_d M_{vir}$, where $m_d = 0.041$ and M_{vir} is the total virial mass. The disks are composed of stars and gas, with a fractional gas content of $f_{gas} = M_{gas,d} / (M_{gas,d} + M_{*,d}) = 0.2$. The stellar bulge(s) have profiles closely approximating a de Vaucouleurs law (Hernquist 1990) and a stellar mass of $M_{*,b} = \frac{1}{3} M_d = 0.27 M_{*,d}$ i.e. close to the observed bulge-to-disk ratio for NGC 4676B of $M_{*,b} / M_{*,d} \sim 0.25$. All stellar and gas particles are embedded in a dark matter halo.

The galaxies contain 240,000 disk particles, 60,000 gas particles (i.e. disk gas fraction of 20%), and 400,000 dark matter particles. NGC 4676B additionally has 100,000 bulge particles, the bulge is omitted from NGC 4676A to match the observations. This leads to a baryonic mass ratio of 1.3, close to that observed in the real Mice galaxies. The baryonic and dark matter particles have masses of $1.8 \times 10^5 M_\odot$ and $3.2 \times 10^6 M_\odot$ respectively.

The initial orbital parameters and time of observation (180 Myr following first passage⁸) were taken from Barnes (2004). The viewing angle was chosen to provide the best match by eye to the CALIFA spatial and velocity maps, using the package SDvision (Pomarède et al. 2008)⁹.

We follow the method of Wild et al. (2009) to assign initial smooth star formation histories to the disk and bulge stars. For bulge stars, we assume a single formation epoch at a look-back time of 13.4 Gyr (the age of the Universe at the redshift of the Mice). The disk stars have close to constant star formation rates, with a slight exponential increase to earlier times to ensure consistency between the current mass and previous star formation history. The simulation then provides the star formation history up until the point of observation, and we extract the spectral energy distribution of each particle using the spectral synthesis models of Bruzual & Charlot (2003). Yields are not tracked in these simulations, so metallicity is kept fixed at solar in agreement with the measured metallicity of the galaxies (Section 6.2). Similarly, attenuation of the starlight by dust is not included due to the many assumptions required, and we compare to observed quantities that have been dust attenuation corrected.

⁸ Snapshots are extracted every 20 Myr.
